Although the neuromuscular diseases of childhood are a heterogeneous group of conditions, there is often a similarity in the causation of pain. Muscle weakness is common and sometimes associated with cramps, which can be distressing and for which simple remedies, such as massage, seem to be the most effective. Most persisting pain in neuromuscular disease is a consequence of the orthopaedic complications of muscle weakness. In particular, pain associated with hip dislocation and progressive scoliosis. Pain can initially be mild in these orthopaedic conditions and simple analgesics sufficient for treatment. With progression, surgical options are often considered and may be more effective for pain relief in the longer term. Occasionally, a few young patients with neuromuscular conditions may require surgery to correct scoliosis or hip dislocation causing severe pain. If surgical options are precluded due to anaesthetic risk, long-term opioid therapy for the management of severe pain may be warranted.

#### Case example: neuromuscular diseases

A 16-year-old boy with Duchenne's muscular dystrophy and severe persisting back pain due to severe scoliosis was reviewed in a pain clinic for children. Corrective surgery was scheduled; however, severe and persisting pain necessitated the administration of a regular schedule of opioid medication. Prior to starting the opioid he was reviewed by his respiratory team as he was being treated with nocturnal non-invasive ventilation for the treatment of hypercapnia. The respiratory team repeated a sleep study which demonstrated the effectiveness of his non-invasive ventilation. The opioid therapy was effective and was commenced under close supervision in hospital. His surgery was completed a few days later and initially he was closely monitored in the paediatric intensive care unit. His postoperative analgesia accounted for the fact that he was needing opioid prior to surgery. His course was uneventful and at the time of discharge simple analgesics were only required for adequate pain control.

### Guillain–Barré syndrome

GBS is an acute immune-mediated polyradiculoneuropathy comprising a broad spectrum of clinical variants (Ruts et al., 2010). It often occurs following a non-specific viral infection and usually results in an ascending paralysis. In developed countries it is the most common cause of flaccid paralysis in children (47%), followed by transverse myelitis (19%), and then a variety of causes, including encephalomyelitis, tick-bite paralysis, and infantile botulism (Morris et al., 2003).

#### Pain in Guillain–Barré syndrome

Data from a prospective study in adult patients with GBS indicated one-third had pain in the 2 weeks prior to the onset of weakness, two-thirds had pain in the acute phase, and 38% overall had persisting pain at 12 months' follow-up (Ruts et al., 2010). Low back and proximal muscle pain, radicular limb pain, peripheral dysaesthesiae, and arthralgias are common in adults; and multiple pain patterns may coexist and overlap, which complicates clinical assessment (Gorson, 2010). Whilst paraesthesiae are commonly

described in children with GBS (Morris et al., 2003), the epidemiology of pain experienced by children with GBS is less well described and the literature is confined to the occasional case report (Pier et al., 2010).

The pathophysiology of pain in GBS is poorly understood. Putative mechanisms include irritation of the nervi nervorum innervating nerve trunks and the dorsal rami, demyelinating of large sensory nerve fibres causing pain dysaesthesiae, and dysfunction of small nerve fibres. Animal studies have suggested a role for T-cell-mediated inflammation and the release of pro-inflammatory cytokines producing thermal hyperalgesia and allodynia (Gorson, 2010). Musculoskeletal pain related to prolonged immobility may also be a contributing factor (Gorson, 2010).

#### Case example: Guillain–Barré

A 10-year-old boy was transferred from a regional hospital to a tertiary children's hospital with a history of weakness in his hands and feet and a complaint of an uncomfortable 'burning' sensation in his hands and feet. The weakness progressed in his limbs proximally and a diagnosis of GBS was made. Concern about progressive respiratory muscle weakness necessitated admission to the paediatric intensive care unit for close monitoring of his respiratory status, but invasive ventilation was avoided and he was discharged from intensive care within 7 days. In the ward he complained of increasing pain related to the dysaesthesiae in his limbs, which was not responsive to simple analgesics. Given the neuropathic quality of his pain he was administered gabapentin. Within 1 week of starting this medication his pain decreased and this greatly facilitated his rehabilitation programme.

### Cerebral palsy

Cerebral palsy (CP) is a diagnostic term to describe a group of permanent, but non-progressive, disorders of movement and posture causing activity limitation. CP may be attributed to a range of disturbances in the developing fetal or infant brain, for example, genetic, metabolic, ischaemic, and infectious causes (Johnston, 2011). The motor disorders are often accompanied by disturbances of communication, sensation, perception, cognition, and behaviour, in addition to epilepsy and secondary musculoskeletal problems (Johnston, 2011).

#### Pain in cerebral palsy

Pain in children with CP is common (Engel et al., 2005) and is associated with a lower quality of life and self-perception (Russo et al., 2008). Therefore, clinicians should enquire about pain in every child with CP and consider appropriate pain management (Riquelme et al., 2011). A recent cross-sectional multicentre European study determined the prevalence and associations of self-reported and parent-reported pain in children with CP of all severities (Parkinson et al., 2010). Children aged 8 to 12 years were randomly selected from population-based registers of children with CP in eight European regions and a further region recruited 75 children from multiple sources. Data on pain in the weeks prior to the survey were available from 490 children who gave self-report and parents of 806 children (who could not self-report) gave their

perception of their child's pain. The estimated population prevalence of self-reported pain in the previous week was 60% (95% confidence interval (CI): 54–65%) and that of parent-reported pain in the previous 4 weeks was 73% (95% CI: 69–76%). Older children reported more pain, but pain was not significantly associated with severity of impairment. In parental reports, severity of child impairment, seizures, and parental unemployment were associated with more frequent and severe pain.

There are many causes of pain in children with cerebral palsy, which can be categorized as:

- ♦ Gastrointestinal (e.g. dysphagia, gastro-oesophageal reflux, constipation).
- ♦ Orthopaedic (e.g. hip subluxation and dislocation, equinus valgus deformities of knee and ankle, scoliosis, kyphosis, contractures).
- ♦ Neuromuscular (e.g. pain related to spasticity, nerve entrapments).
- ♦ Rehabilitative (e.g. pain related to the physical therapy activities of stretching and bracing).

Pain treatment strategies should be directed at the specific causes listed and if analgesic agents are needed, the general principles outlined at the beginning of this chapter are applicable. The diagnostic process may be difficult, and a case has been made to obtain a whole-body technetium bone scan in children with CP for whom there is no obvious case, as occasionally occult fractures may be identified (Bajelidze et al., 2008). Novel treatments for pain related to spasticity include botulinum toxin type A injections (Lundy et al., 2009) and intrathecal baclofen (Hoving et al., 2009a, 2009b).

#### Case example: cerebral palsy

A 12-year-old girl with severe CP presented to the ED with behaviours indicating to her care-givers that she had severe pain. Normally a happy child she had a 48 h history of inconsolable crying and grimacing facial expressions. Previously diagnosed comorbidity included gastro-oesophageal reflux which was being treated with a proton pump inhibitor and subluxed hips for which surgery was not intended in the near future. Apart from demonstrating signs consistent with severe CP her clinical examination revealed severe hip adductor muscle spasm. The centrally acting muscle relaxant baclofen was administered regularly and her pain behaviours improved dramatically.

## CHAPTER 33

# Common pain problems in the outpatient setting

F. Ralph Berberich and Neil L. Schechter

### Summary

This chapter will review key concepts pertaining to paediatric pain relief in office settings. Included are general principles important to achieve pain reduction, pain attributed to normative developmental processes such as teething, colic, and 'growing pains', pain from infections such as otitis media and pharyngitis, and pain from minor procedures.

### Introduction

Unfortunately, many advances in paediatric pain management have not been applied to the paediatric office (Berberich and Schechter, 2012). For example, despite their exponential increase in number, immunizations are often still administered in a manner similar to the way they were 40 years ago, continuing to contribute to a rate of needle phobia of 10% or more. Furthermore, little research has been done on relieving the pain of otitis or pharyngitis, common problems which are a significant source of discomfort. The reasons for this are manifold but certainly due at least in part to the less dramatic and often ephemeral nature of pain in the office. There exists additional concern that systematically addressing these issues might reduce office productivity and efficiency. Despite these barriers, addressing pain may prevent some of its short- and long-term consequences. Additionally, attention to pain is likely to enhance the relationship between the physician and the child and his or her family (Schechter et al., 2007).

### General principles

The office based clinician, who typically has a long-term relationship with the child and family, and is well versed in child development, is in position to incorporate the principles of pain reduction into the practice setting. By doing so, he or she can lower the cumulative impact and memory of repeated 'minor' painful insults (Von Baeyer et al., 2004). He or she can perhaps prevent the development of needle phobia, teach parents to provide comfort for their children, and reduce the anticipatory fear and anxiety that often surrounds visits to a health care professional (Schechter et al., 2010). Development of a paediatric office that routinely employs the following principles will improve the quality of life not only for the child and his or her family but also for the paediatric office staff (Schechter et al., 2010).

### There is enormous individual variability in response to a painful stimulus

Pain is a complex multifactorial phenomenon with enormous variation from person to person. There is no predictable level of pain response for a given nociceptive stimulus. The pain experience for any child is a composite of various factors including temperament, age, previous experience, parental response, social modelling, genetic predispositions, and psychological state (Blount et al., 2008; McMurtry et al., 2010; Schechter et al., 2007, 2010). A clinician who knows the child and family well can anticipate how the child might respond based on unique attributes of the child and his or her previous response to painful procedures. Clinicians also can benefit from the parent's in-depth knowledge of the child. Awareness of prior reactions, temperamental characteristics, and family dynamics may suggest non-pharmacological strategies and stave off more aggressive interventions.

### Explanation and guidance regarding pain may help reduce it

Anticipatory guidance has become a cornerstone of paediatric practice. Although children display significant individual differences, they develop, in general, predictable sequences that allow us to anticipate what their challenges will be. Routinely incorporating information about pain into well child visits may allow children and families to prepare for, and appropriately cope with, the painful experiences that arise during childhood. This includes identifying helpful individualized strategies as well as recognizing when analgesics may be of value, and how best to use them. Two of the constructs are discussed in the following two sections.

### Anticipate and/or prevent pain whenever possible

The importance of anticipating pain and the prompt use of pain reduction strategies should be emphasized at the outset of the physician-patient relationship. Pain may be more easily controlled if it can be prevented or addressed early on. Clinicians should give information about medication dosing and safe intervals between doses. Parents should understand that pain medication can be given proactively in anticipation of pain after injury or during illness or before procedures such as venepuncture. When a medication is appropriate for either pain or fever, parents should be instructed not to omit that medication 'because there is no fever'.

### Promote self-mastery in the child

Teaching children techniques that can allow them to control their pain decreases the helplessness that they may feel when confronted with a painful situation. The clinician periodically can support and reinforce the importance of participatory distraction and encourage parents to identify the most appropriate and effective coping measures for their child. They best know their child's temperament, and the strategies that have been effective previously. Measures such as singing a song together, reading a story, watching a video, are ways to reduce the 'bother' and trauma of a painful or frightening event. These techniques, as well as others incorporated into an immunization sequence, can diminish the pain response and its associated anxiety (Berberich and Landman, 2009). Many of these techniques could be practised at home to enhance their mastery. As the child grows, the clinician can remind parents to bring along stuffed animals, books, or smartphones and to help engage in self-calming non-procedural talk and activities. Parents should learn that it helps to look forward to something pleasurable, i.e. 'When we've finished here, then we can ...'

### Attention to the language and demeanour of the clinician and the parent is critical

Language and demeanour have a critical role in shaping the child's experience of, and response to, painful situations. Children readily read verbal and non-verbal signals, such as facial expressions, tone, pitch of voice, whether a sentence rises or falls, and the degree of confidence and security displayed by a parent (Blount et al., 2008). If the content of what is said is at odds with the non-verbal message, the child may be confused and suffer uncertainty and paradoxical anxiety. Parental demeanour projecting excessive worry and a sense of catastrophe often will cause exaggerated responses in children (Vervoort et al., 2011a, 2011b). Parental modelling can contribute to the development of fear and enduring phobias (de Roznay et al., 2006). Therefore, parents should be advised to be cognizant of their own attitudes towards pain and how any negative prejudice or anxiety might be transmitted to their child.

Words uttered in the doctor's office have greater than expected impact (Berberich, 2007). Parents and clinicians should be aware that children might take to heart what may seem like relatively 'innocent' analogies such as 'like a bee sting' (Berberich and Schechter, 2011) or statements that conflict with what the child is thinking, such as 'It's OK' or 'Don't worry'. It is far better to instruct parents, pointing out the nuances of language as well as the possible contradiction between intent and effect when speaking to children. In particular, a frightened child may hear as a threat what is actually intended only as a light-hearted parental tease, so the clinician should respond appropriately to comments of this kind. Curiously, there is evidence indicating that excessive reassurance is not always reassuring and over-empathizing may actually increase anxiety and discomfort rather than diminishing them (Schechter et al., 2010).

### Parents have a critical role to play in pain reduction

Parents should be encouraged to be active, supporting participants in every medical encounter and be informed how they can be most helpful. We have learned that parents, when properly informed and respected, can play an essential role in the reduction of the pain problems. Parents can help us identify the type and timing of preparation that seems most effective. They can practise now-familiar distraction techniques at home and use these to coach the

child through painful procedures in the office. When medically safe, upright comfort positioning, often on a parent's lap, is the best choice for the examination or any procedure that could be seen as invasive (Lacey et al., 2008; Schechter et al., 2007; Sparks et al., 2007). If restraint on an exam table is required, positioning a parent near the child's head and seeking cooperative possibilities reduces anxiety.

### Analgesics in the outpatient setting

The judicious use of pharmacological agents remains a mainstay of successful pain treatment. Acetaminophen (paracetamol, APAP) and non-steroidal anti-inflammatory drugs (NSAIDs), typically ibuprofen, constitute the primary first line agents. They are considered to be equally safe although ibuprofen may be a bit more effective (Pierce and Voss, 2010). Until there is sufficient evidence to support one agent over another, a step wise approach, similar to the World Health Organization pain ladder, seems reasonable when pain persists despite a properly administered single agent. This entails adding one agent to the other at safe dose intervals (Wright and Liebelt, 2007). While there seems to be no antipyretic advantage to an 'alternating' 3 h acetaminophen/ibuprofen schedule other than its perceived simplicity (Wright and Liebelt, 2007), analgesia may be enhanced by utilizing both in combination (Ong et al., 2010). To avoid confusion, written administration plans are advisable (Wright and Liebelt, 2007). Physicians need to prepare parents so that they completely understand how to use these medications and neither overdose nor underdose. Handouts or office web sites for parents are often helpful.

The clinician may face situations in which pain is not treated adequately with acetaminophen or NSAIDs. Oxycodone and hydrocodone deliver predictable and potent levels of analgesia and are available in liquid preparations. Despite the lack of clinical trials and potential concerns about opioid abuse, fear of untoward outcomes, and lack of published guidelines, paediatricians and family physicians should be prepared to consider these opioids when faced with moderate to severe pain. Tramadol (Ultram™) is an atypical opioid that has been used safely and effectively in children at an oral dose of 1 to 2 mg/kg every 6 h. Those who treat children should not prescribe codeine-containing medications because of its ineffectiveness in many children and toxicity in some. Inert codeine is metabolized to its active metabolite, morphine at a 10:1 ratio in 'normal' metabolizers. However, there are clinically significant, even fairly large, numbers in whom the CYP2D6 enzyme responsible for that metabolism is genetically altered. In many individuals, up to 30% of the general population, this enzyme variant of CYP2D6 results in poor metabolism, which translates to ineffectiveness. In others, especially those of North African descent, ultrarapid conversion to morphine may result in toxic levels and a risk of mortality (Kelly et al., 2012). All opioids tend to produce constipation and this side effect is best anticipated with consideration of stool softening and laxative agents. Pruritis, hallucinations and dreams, and somnolence should be encountered relatively less frequently in outpatients receiving appropriate doses and short courses.

Table 33.1 lists step-up groupings of common pain medications applicable to the paediatric office setting. These will have a variety of trade names and formulations. Opioids are regulated in most countries and may require special prescription forms. One must be especially cautious when prescribing combination opioid medications that may include other analgesics, decongestants, or

**Table 33.1** Paediatric oral pain medications (formulations may vary)

Drug	Dose (mg/kg)	Interval (h)	Suspensions (mg/ml)	Tabs (mg)
APAP	15	4–6	160/1 160/5	160, 325, 500
Ibuprofen	10	6–8	100/5	200, 400 600
Tramadol	1–2	4–6	N/A (US)	50, 100–300
Hydrocodone	0.1–0.2	4–6	2.5/5	2.5, 5, 10
Hydromorphone	0.05	4–6	5/5	5
Oxycodone	0.1	4–6	1/1	5

antitussives. For example, Lortab® elixir contains hydrocodone 2.5 mg per 5ml, but also has APAP 167 mg, requiring dose adjustment of any concurrent APAP for pain or fever. It also contains 7% alcohol. In addition, any condition that affects drug metabolism or concurrent medication such as diphenhydramine, atropine, or some psychotropic drugs may compound or mask common side effects such as somnolence, nausea, and pruritis.

It is important to alert families to formulation variance, idiosyncratic dropper markings, expiration dates, the importance of closing childproof containers, and proper disposal of unused opioid medication. Parents should be encouraged to consider pain apart from its cause and an independent symptom that calls for independent attention. It is still the case that parents sometimes withhold pain medication for fear that important symptoms may be masked and the validity of the physical examination compromised (Bromberg and Goldman, 2007). It may be appropriate to introduce general guidelines for analgesic medications early, perhaps coinciding with immunizations at 2 months of age. Periodic reinforcement can be provided at intervals during well child visits.

## Pain associated with specific conditions

In the following section, specific pain problems will be reviewed. These include pain arising from the evaluation and treatment of specific disease states, pain that stems from normative processes, and pain from commonly performed procedures. Needle procedures are discussed elsewhere in this text (Taddio, Chapter 19).

## Pain stemming from specific disease processes

### Otitis and otalgia

Acute otitis media (AOM) is the most common cause of childhood physician visits in the US, generating 16 million outpatient encounters and 13 to 15 million prescriptions per year, as well as significant financial costs (Woodwell and Cherry, 2004). Additionally, about 2.4 million US healthcare visits occur for the treatment of acute otitis externa (AOE) (Centers for Disease Control and Prevention (CDC) 2011a).

Common to both entities is otalgia, which is often quite intense (Narcy et al., 2006). The structures of the external canal, middle ear, and tympanic membrane contain a wealth of nociceptive innervation responsive to inflammation and pus under pressure (Zempsky and Schechter, 2000). Antibiotics do not have a rapid or profound effect on the resolution of pain (Spiro et al., 2008). While controversy continues to surround recommendations for the institution and choice of antibiotics, the treatment of otalgia remains a pressing concern, especially for parents confronted with crying children and sleepless nights.

Systemic oral analgesics are recommended first. Most commonly, these are acetaminophen, ibuprofen, or combinations of both, as previously described. It may take up to an hour for acetaminophen and ibuprofen to become noticeably effective. In the case of AOM without perforation, local analgesic therapy may bridge this gap and allow for rapid comfort. In the US, Auralgan® (antipyrine, benzocaine, and glycerine) is popular for this purpose, although definitive benefit remains to be established. A double blind, randomized, placebo-controlled paediatric study using topical aqueous 2% lignocaine showed a 50% reduction in pain scores from baseline at 10 and 30 min (Bolt et al., 2008) but the validity of the study has been challenged (Bharti and Bharti, 2008). In a non-controlled multicentre observational study of a little over 400 children, most of whom had AOM, another comparable analgesic, procaine with phenazone yielded physician rated efficacy of 'good' or 'very good' in more than 95% (Adam et al., 2009). However, an earlier Cochrane review found insufficient evidence to support the effectiveness of either topical analgesia or naturopathic herbal eardrops (Foxlee et al., 2006). Clinicians confronted with intractable otalgia should be prepared to utilize opioids, as they are likely to be effective.

In AOE, it seems clear that antibiotic ear drops with or without hydrocortisone plus suspension of water exposure leads to the most rapid resolution of pain as well as the infection (Roland et al., 2008). A variety of warm oils and hot compress applications may provide transient symptomatic relief, but have not been tested rigorously.

Otalgia is a common occurrence and parents should be educated about pain treatment in advance of the first ear infection. In a report describing an education program at the 15-month well-child examination, to which was added a proactive prescription for antipyrine-benzocaine otic drops (Auralgan®), the study group experienced reductions of 80% emergency room, 40% urgent care, and 28% primary care visits for otalgia (McWilliams et al., 2008).

### Acute pharyngitis

In a sample of 160 families that included approximately 240 children, 41% experienced at least one episode of acute sore throat in a 16-month prospective study period (Danchin et al., 2007). Bacterial infection, notably by group A *Streptococcus* accounts for roughly 20% to 35% of pharyngeal infections (Shaikh, et al., 2010). While the literature is replete with articles about group A streptococcal disease, evidence-based pain management protocols are lacking. This persists despite the observation that antibiotics do little to ablate pharyngeal pain.

Pain control here as with many other conditions begins with the administration of oral analgesics, specifically acetaminophen and ibuprofen. Medication may be harder to give because of pain

and dysphagia, or from illness-associated vomiting. When either is prominent, rectal acetaminophen may be the better choice. Although most pharyngeal pain resolves by 48 h, prescribing around-the-clock analgesic increases that resolution from 55% to more than 70% (Bertin et al., 1991). Tramadol or opioid-ibuprofen/acetaminophen combinations may be indicated to relieve refractory pain and maintain hydration.

The treatment of mononucleosis-associated exudative tonsillitis may require maximum analgesia efforts. Once a presumptive diagnosis is established, a short course of steroids may provide relatively rapid relief. Steroids have been found effective for other forms of severe pharyngitis as well (Korb et al., 2010). In two randomized clinical trials in which paediatric patients received dexamethasone, 0.3 mg/kg to 15 mg maximum (Roy et al., 2004), or 0.6 mg/kg single dose to 10 mg maximum (Olympia et al., 2005), versus placebo, sore throat resolved earlier and faster, whether or not patients tested positive for group A *Streptococcus* or mononucleosis.

Lozenges and cough drops designed to soothe throats are not advised for children under the age of 4 years or for others in whom there is an aspiration risk. A transient benefit for older children may be presumed to represent benign intervention, but no studies actually exist to demonstrate pain relief or significant soothing. A randomized clinical trial in adults undertaken in the UK showed about 2 h relief from amylmetacresol/2,4 dichlorobenzoyl alcohol lozenges (McNally et al., 2010.) Some practitioners or parents may favour herbal preparations or a variety of home remedies, but their safety and efficacy likewise still need to be tested.

### Gingivostomatitis

In children, stomatitis, faecal ulcers and gum swelling, are commonly associated with primary herpes simplex or herpangina due to Coxsackie infections. A majority of children will have had primary herpes simplex or another form of viral pharyngitis by age 5 years. Pain and reluctance to eat and drink are the primary symptoms of concern, as the illnesses themselves typically run a benign course.

Analgesic medications, acetaminophen and ibuprofen, may be prescribed around the clock and timed to reach peak effect at mealtimes. If dehydration or inadequate oral intake result, opioid combinations or intravenous rehydration may be necessary. Acidic foods such as citrus or vinegar may cause pain. Milk-based shakes or their equivalent may be preferred to solid food. Depending on the location of lesions, drinking through a large straw may be accepted.

Acyclovir may shorten the duration and thus indirectly affect pain (Faden, 2006). A number of topical medications can be prescribed, most of them derived from experience with chemotherapy and radiation-induced stomatitis. The rationale behind these agents is to coat exposed ulcers. Thus either diphenhydramine-bismuth subsalicylate (Kaopectate®), or diphenhydramine-aluminium/magnesium hydroxide is often used on an anecdotal basis. There are no published prospective trials comparing the treatment options.

Viscous xylocaine 2% is attractive for its numbing properties but carries a theoretical risk for aspiration and the possibility of a child biting his own buccal mucosa. There have been documented toxicities, some fatal, due to overdose or swallowing rather than 'swish and spit' (Curtis et al., 2009). Application of the lidocaine directly to the lesions may be safer, but saliva is likely to carry at least some throughout the oropharynx and therefore entail the same risks.

### Pain associated with normal growth and development

Certain events are so often encountered during the course of normal growth and development that it is hard to consider them abnormal. However frequency does not dismiss the significance and validity of the pain experienced. Few interventions have been identified as efficacious for these problems and reassuring parents of their benign nature and supporting them through these episodes is perhaps the most valuable contribution that the clinician can make.

#### Colic

Colic was defined almost half a century ago by the rule of 3s, coined by Wessel as excessive crying and fussing for more than 3 h per day, more than 3 days a week, for more than 3 weeks' duration. Colic is one of childhood's most disconcerting, yet physiologically benign, conditions, occurring in up to 20% of infants (Shergill-Bonner, 2010). There are those who maintain that colic is not painful, but rather a state of pain-unrelated excessive crying without identified cause (Lucassen and Assenfeldt, 2001). Despite its unknown aetiology, there seems to be agreement that abdominal distress is associated with amplifying aerophagia and distension. No medication resolves colic and there also is no other proven standard therapy (Hall et al., 2011). Herb teas and similar preparations such as fennel-containing gripe water are often suggested, but none have been studied systematically. Other approaches such as formula alterations, probiotics, acupuncture, chiropractic manipulations, and massage have been advocated by some (Arikan et al., 2008), but remain unsupported by evidence.

Measures undertaken by clinicians currently seek to minimize parental distress, maintain bonding, and offer reassurance as to the absence of long-term consequences (Keefe et al., 2006). Dietary alterations only help if there is an identified intolerance. (Shergill-Bonner, 2010). Interruption of breastfeeding or multiple formula changes may be undesirable consequences of well-intentioned interventions. Given the frustration of parents, a variety of unproven interventions such as gentle rocking while pacing, long rides in the car, swaddling and 'shushing' (Karp, 2007), competing noise such as that generated by a vacuum cleaner, and parental ear plugs, all continue to be suggested.

#### Teething

A variety of behaviours, such as irritability, intermittent crying, and increased chewing may indicate teething during the first 6 months of life (Feldens et al., 2010), although the caveat is that these may also be part of normal development. Much is falsely blamed on tooth eruption, especially by parents surrounded by teething lore (Owais et al., 2010). Prospective cohort studies have revealed only weak association with previously reported symptoms, and no association with severe illness (Ramos-Jorge et al., 2011). Local pain and low-grade fever may be attributed to teething legitimately only by a process of elimination.

Oral ibuprofen and acetaminophen have long been used to treat teething pain, especially when it interferes with sleep. Opioids are not recommended because there is no evidence for efficacy in the setting of a relatively mild, yet protracted condition. Parents may be cautioned that a baby who immediately soothes when picked up may not be suffering from teething pain. There is no evidence that topical and homeopathic preparations, ice pack massages, or

frozen foods applied locally provide effective relief. However, frozen solid, non-phthalate containing teething rings, hard apples, frozen bagels, are popular. Agents containing lidocaine, benzocaine or comparable anaesthetics can be toxic, rarely associated with methaemoglobinaemia, even occasionally lethal (Curtis et al., 2009). Some teething gels have been associated with salicylate toxicity (Williams et al., 2011). Although widely available, there is no evidence to support herbal and other over-the-counter teething remedies.

### Growing pains

The term describes a poorly understood syndrome of recurring bilateral lower limb discomfort, typically occurring at night in active children during the pre-pubertal growth years. The incidence is estimated at 10% to 20% between the ages of 3 to 12 years, with a peak occurrence between ages 4 to 8 years (Goodyear-Smith and Arroll, 2006). The pain may be sufficient to awaken the child. Characteristically, there are no physical findings and no other limbs or muscle groups are involved. Children are asymptomatic during the day. The diagnosis is made by exclusion; yet the recurring nature of symptoms without anatomic explanation may arouse anxiety on the part of parents and this in turn may intensify symptom reports. A recent literature search disclosed the absence of evidence to endorse any particular form of therapy (Evans, 2008). Systemic oral analgesics such as ibuprofen or acetaminophen may be administered in conjunction with local measures such as massage, stretching, and warmth. The latter may be accomplished with heavy-duty cotton, wool, or polyester socks that extend over the calf. To enhance warmth, these can be preheated in the dryer. Microwaved heat packs may be useful, but need to be assessed for hot spots before being applied.

## Pain associated with common procedures

### Circumcision

Surgical removal of the penile foreskin is probably the most common, and controversial perinatal procedure in paediatrics. In the US, roughly half or 1.2 million male newborns are circumcised each year. For about one-fifth of the world's population, circumcision is a religious expectation. There is recent data suggesting circumcision may contribute to a reduction in the incidence of HIV/sexually transmitted infections (Bailey et al., 2007) and this may in turn signal an increase in its acceptance (CDC, 2011b). Medical, ethical, and legal pros and cons aside, the issue of pain management persists, whether circumcision is carried out in the office, hospital, or elsewhere.

Recently, the American Academy of Pediatrics issued a policy statement, which reaffirms the appropriateness and specifics of proper analgesia (American Academy of Pediatrics, 2012). The American Academy of Family Physicians (AAFP), American College of Obstetricians and Gynecologists, Canadian Pediatric Society, British Medical Association, and the British Association of Paediatric Urologists have issued comparably supportive policy statements. Without analgesia, circumcision causes physiological signs of marked distress, such as elevated heart rate, blood pressure, and plasma cortisol, increased crying, and augmented reactions to painful stimuli in infancy (Taddio et al., 1997).

Taddio summarized the influence of circumcision technique and topical and local anaesthetics on the attenuation of this distress. Circumcisions were performed with one of three clamps, the

Gomco, Plastibell, or Mogen. Local anaesthesia infiltration consisted of dorsal penile nerve block (DPNB), ring block, or topical anaesthesia. DPNB is carried out in a fairly standardized manner with 1% lidocaine without adrenaline 0.2 to 0.5 ml delivered at the 10:00 and 02:00 position subcutaneously at the base of the penis penetrating Buck's fascia (Kirya and Werthman, 1978). A circumferential ring block is performed with the same lidocaine injected mid-shaft or behind the corona.

Choice of clamp may reflect operator training, degree of comfort, or perceived risk of performing the procedure as much as evidence-based data. In combination with DPNB, the Mogen clamp entails less pain and a shorter procedure time than the Gomco clamp (Kurtis et al., 1999).

Taddio has summarized the substantial data confirming the effectiveness and safety of DPNB (Taddio, 2001) versus placebo or no treatment. A 1997 randomized clinical trial compared pain using a ring block, DPNB, and topical lidocaine-prilocaine cream. The study showed an advantage for ring block in that it alone was effective for the foreskin separation and incision phases of circumcision (Lander et al., 1997).

What topical analgesia gains by being simple to use, effective, and portable, it loses as it provides relatively poor analgesia during the brief probe lysis of glans adhesions. The duration of the pre-procedure application of topical anaesthetics influences the clinical outcome. Taddio has cited a range of 45 to 90 min as well as a dosage range of 0.5 to 5 g (Taddio, 2001). However, the depth of anaesthetic effect relates to the duration of application and is greater with longer wait times of up to 120 min in at least one adult study (Wahlgren and Quiding, 2000). There does exist the theoretical potential for methaemoglobinaemia related to prilocaine, however the clinically significant risk has been estimated to be 0% (Taddio, 2001). Liposomal lidocaine cream (LMX-4) also has been shown to be safe and effective, comparable to lidocaine-prilocaine cream in a randomized trial (Lehr et al., 2005).

A Cochrane Review evaluated 35 trials involving 1997 newborn males to generate best evidence conclusions regarding efficacy of pain interventions (Brady-Fryer et al., 2004). The meta-analysis indicated that DPNB and lidocaine-prilocaine cream both reduce circumcision pain when compared to placebo and that DPNB is relatively more effective than lidocaine-prilocaine cream applied for 60 to 90 min. However, strict comparability of studies was rare as the choice of clamp utilized and length of wait time varied.

Additional measures to lessen discomfort include non-nutritive sucking, sucrose, and having the baby securely and properly held by a person as opposed to a plastic moulded restraint (Stang et al., 1997; Taddio, 2001). Acetaminophen may be effective postoperatively, but has little effect before the procedure (Taddio, 2001).

### Cerumen impaction

Excessive earwax may impede the accurate diagnosis of middle ear disease. Its mechanical removal can cause pain, trauma, and bleeding. A 2004 literature review and meta-analysis of adult and paediatric studies showed a 40% clearance rate when water or oil-based otic cerumenolytic agents were instilled for several days. A 2009 Cochrane review indicated that while otic wax removal drops were more effective than water, none stood out as being superior to any other (Burton and Doree, 2009). In order to avoid being confronted with an acute need to remove cerumen, a clinician can begin dealing with it whenever it is noted. Instilling

over-the-counter cerumenolytics several times a week during sleep may prove useful, as long as there is no otorrhoea. Faced with blocked ear canals in the office, irrigation with saline, plain water or a 50:50 hydrogen peroxide/water mixture has been found to be effective; however, electric irrigators produce noise that may frighten some children and the sensation of water flooding the external canal may prove unpleasant for others. Preceding irrigation with a 10 min instillation of liquid ducosate sodium (Colace®) may aid cerumenolysis, but this method has not been studied systematically. Published guidelines do not indicate a preference or endorse one removal method over another (Hand and Harvey, 2004; Roland et al., 2008). There is no demonstrable efficacy to support a variety of folk remedies such as the instillation of oils and garlic. Others, such as candling are ineffective and can cause injury (Zackaria and Aymat, 2009).

### Urinary catheterization

Despite its imperfections sterile catheterization remains the gold standard to diagnose urinary tract infection (UTI; Wingerter and Bachur, 2011). Suprapubic aspiration is associated with pain and a tendency towards more procedure failures than urinary catheterization (El-Naggar et al., 2010). In a randomized controlled trial, the administration of oral sucrose reduced pain scores and showed a relatively more rapid return to baseline in infants less than 30 days of age (Rogers et al., 2006). However, this beneficial effect was not apparent beyond the first month of life.

In addition to catheterization for UTI diagnosis, this procedure is an integral part of the voiding cystourethrogram (VCUG). New guidelines could reduce the necessity for VCUGs (Schroeder et al., 2011), but not entirely eliminate them. Topical 2% lidocaine gel instillation may reduce catheterization pain (Vaughan et al., 2005), although the evidence is mixed in clinical trials. Even though VCUGs are not conducted in the paediatric office, the clinician may become involved by preferentially referring patients to institutions that attend to the associated discomfort. A 2005 randomized study reported effectiveness of hypnotic relaxation in children who had a prior VCUG and were more than 4 years of age (Butler et al., 2005). Successful sedation with 70% nitrous oxide (Zier et al., 2007), intranasal fentanyl (Chung et al., 2010), and midazolam (Herd, 2008) has been reported, although others question whether it is beneficial for the properly prepared child (Sandy et al., 2011). The decision might best be individualized by the physician who actually knows the patient. For some, offering preparation, procedural narration and distraction (Salmon et al., 2006), often the province of child life specialists, may be an appropriate stand alone or supplemental choice.

### Cauterization and foreign body removal

Intranasal silver nitrate cauterization for epistaxis can cause discomfort. This and nasal swabbing are both swift, but the stinging and sneezing can be quite unpleasant. Clinicians often are faced with having to retrieve a pea or bead from a nostril. Similarly, obtaining a nasopharyngeal sample by means of a swab may be considered invasive. Where indicated in a fearful child, topical 4% lidocaine delivered by means of a reusable bottle metered dose atomizer with a disposable applicator (MADomizer™) may be acceptable prior to instrumentation. Alternatively, anaesthetic solutions can be compounded 50:50 with a nasal decongestant containing oxymetazoline.

### Tick removal

Some children may be disturbed by the sensation of skin tenting during removal by traction. Others may seek rapid removal knowing an insect has attached and burrowed into their skin. A 4 to 10 sec spray of vapocoolant (PainEase®) may relieve pain and provide kinaesthetic distraction as well.

### Ocular foreign body and corneal abrasion

Proxymetacaine anaesthetic drops can facilitate examination and provide a more accurate diagnosis of foreign body (Sklar et al., 1989). A temporary burning sensation may still be experienced. Anaesthetic drops are instilled only for diagnosis, and not for treatment, because of toxicity and sensitization risks. Patching the eye often stops the pain.

### Subungual hematoma

Subungual hematomas cause pain secondary to pressure, which can be relieved by creating a hole in the affected nail. This may provoke anxiety, but should not be painful when accomplished by means of a hand-held single-use cautery (Bovie®). The cautery tip is gently applied to the nail over the hematoma in short bursts, following the manufacturer's safety directions, until sufficient penetration allows the underlying blood to extrude. A trephining drill or rotating needle can accomplish drainage as well, but some pressure is required and this itself causes pain and potential anxiety, while other associations such as drill with needle may arouse fear or panic. Children should be told in advance and shown that the nail feels no pain.

## The 'pain-sensitive' office

By systematically incorporating the previously described principles and strategies into practice, the burden of pain in the paediatric office can be reduced significantly. Additionally, attention to the office environment, physician and staff participation and a general declared emphasis on pain reduction can make a difference.

### Office environment

It stands to reason that the best paediatric office milieu is one that is cheerful and non-threatening, or better yet, calming, both in its physical surroundings and in the demeanour of its personnel. Most practitioners assume that age appropriate toys, books, and media that utilize innate curiosity can do much to put children at ease. Given the relationship between anxiety and pain perception, environmental props and office flow policies that generate a mood of calm could be expected to have an impact on that anxiety, for better or for worse. Yet there is no data establishing precise formulas for how those are to be constituted.

As most children often wait in examination rooms after leaving the waiting area, the same kind of props should be available in that location. There is no direct evidence favouring one colour scheme or set of books and magazines over another, and this would be hard to come by as cultural, age, and individual preferences all vary widely, and gender also influences choices. It nevertheless remains a worthy goal to seek the means to divert the child's attention from preoccupation with the pending examination, immunizations, and other disquieting procedures or treatment (Berberich and Landman 2009; Du et al., 2008; Schechter et al., 2007).

An environment rich in distracting materials may be helpful in shifting focus, especially as it allows, even encourages, parents to engage in non-procedural talk (Schechter et al., 2007). Although supporting data are lacking, the choice of wall colour, posters and

images likely can do much to support a sense of comfort and familiarity and engage the child. When choosing the elements that will characterize the office and examination rooms, the suggestibility of children should be kept in mind although the evidence for positive effect is mixed (Berberich and Landman, 2009; Kohen and Olness, 2011). By posting photographs of patients and families, children can recognize themselves, perhaps their friends, and be given an anxiety-tempering message of normalcy and familiarity. Similarly, posters of animals or amusing cartoons provide suggestions of levity and arouse interest.

Children's affinity for animals, how they uniquely relate to them, and their assignment of animals to characters and 'personality' traits are themselves subjects of study (Melson, 2005). Some may be associated with bravery (lions, tigers), others with nurturing (birds in a nest, mother bears and cubs), and yet others with coziness (puppies, kittens). Children readily absorb the messages that such stories and images provide. Further, they may use associations and implications to change behaviours (Wansink et al., 2012). Since so many children gravitate towards inanimate representations of animals to provide emotional support and security (Triebenbacher, 1998), having a stuffed, easy-to-wipe-down, office 'mascot' to cuddle may provide yet another useful prop.

### Office Pain 'Champion'

Even if an office has committed itself to being 'pain sensitive', it is helpful to identify a pain champion who can recruit the ongoing participation of colleagues and staff, remain current by reviewing paediatric pain literature, and set the tone for staff commitment to foster comfort (Kuttner, 2010; Schechter, 2008). That dedicated clinician can generate appropriate literature for parents and educate the office staff in order to maintain a pain minimizing focus. For patients with chronic pain conditions, pertinent books and web site links can be made available. In complex situations, the office pain champion can become an in office consultant and guide appropriate referral to a paediatric pain specialist (Berberich and Schechter, 2012).

### Proactive pain management

Because of the negative conditioning effect of pain, and simply because it causes distress, its infliction should be avoided wherever possible, especially in very young children (Schechter, 2008; Zempsky and Schechter, 2003). A proactive approach might be termed anticipatory anticipation! A prime example would be to prescribe 2.5% lidocaine-prilocaine cream or 4% Lidocaine (LMX-4®) cream together with instructions for a 90–120 min covered application before elective blood draws such as lead level determinations. Parents can apply these agents at home, eliminating the need for office application and the wait time, and thus reducing barriers to their use. Similarly, parents of infants can be reminded before the 2-, 4-, and 6-month visits about acetaminophen or ibuprofen administration after immunizations, as well as how to apply local measures such as cool compresses. At the 12-month visit, when toddlers begin to walk and stumble and injure themselves, the clinician can remind parents to use local measures and medicate early for 'minor' pain. Because the crying associated with pain is so unnerving, repetition serves to embed the parents' responses in a way that these become more automatic and prompt. Teaching appropriate consolation could shorten the distress associated with injections, inducing more rapid resolution of pain and possibly

affecting the degree of negative conditioning that result from it (Harrington et al., 2012). The development and dissemination of evidence-based, online, video, and written material instructing parents how to approach medical office visits and uncomfortable procedures would be most welcome.

### Attention to comfort

In the pain-sensitive office, comfort measures such as nursing, non-nutritive sucking, and sucrose administration are supported (Pillai Riddell, et al., 2011). Easy access to oral 24% sucrose (Sweetease™) or topical anaesthetics will promote their use. Respect for a child's autonomy tempers fear as does parental proximity. Until it becomes a yes or no option for a curious child, the examination table is best avoided unless absolutely necessary. Being supine with a physician hovering over you can be intimidating. The timesaving importance of allowing children to adopt positions of security has been identified in the context of IV placement (Sparks et al., 2007). Most paediatricians become quite adept at demonstrating instruments and creating games as part of the physical examination. They will already have learned to save the most invasive parts of the exam for last. The active participation of the child is one of the best routes to cooperation. Areas of pain are best approached gradually and with careful attention to facial expression and body language. Posting signs and web site information indicating that the office is committed to addressing pain emphasizes commitment.

### Communication about pain

There is no uniform agreement as to what constitutes authenticity and honesty when kids ask about procedures that may cause discomfort. Deceit and trickery permanently destroy trust. Yet 'informing' can be phrased as a negative or positive suggestion, even taking into account the unpredictable individuality of each child. Therapeutic language is that which is crafted to elicit positive coping responses. That skill is taught, among others, by experts in the field of paediatric hypnosis, which, together with biofeedback, can be useful for procedures (Butler et al., 2005) and for acute and chronic pain (Kohen and Olness, 2011). In the United States, the National Pediatric Hypnosis Institute and the American Society for Clinical Hypnosis currently provide training workshops. The Milton Erickson Society of Germany is also active in promoting paediatric hypnosis instruction.

## Conclusion

In this chapter, we have sought to coalesce some of the limited available information on pain treatment in paediatric outpatient facilities. While recognizing the need for additional research, uniform application of what we already know will go a long way toward reducing the burden of outpatient pain. Despite perceived obstacles and past patterns of indifference, pain in paediatric offices can and should receive the attention it deserves. What is required is a long view, one that acknowledges the significance of the 'little' insults that can be avoided with a bit of effort and the expenditure of a small amount of time. Attention to pain can improve the doctor/patient/family relationship by rendering a child more cooperative and less frightened. That leads to an adult who feels more comfortable within the medical system rather than fearful and avoiding of it. Every clinic setting deserves a pain 'champion' to prod all those delivering the health care at that facility to be mindful of, and proactive in, dealing with pain.

### Case examples, with and without a pain-sensitive approach

A 2-year-old girl presents crying with an earache and a temperature of 39°C having slept poorly and received a single dose of acetaminophen during the previous night. The doctor examines the patient and finds the ear canal occluded by cerumen. He takes a plastic curette and places it in the external canal to remove earwax. The child jerks her head and cries out in pain. The child appears upset and her mother asks, 'Did that hurt her?'. He tries again and notices that there is some bleeding in the external canal. Still unable to see, he orders an ear wash. The child cries throughout. When the doctor returns, he is still unable to visualize the tympanic membrane, and the child writhes and cries loudly each time he approaches to insert the otoscope. He prescribes a course of amoxicillin, telling the parent that the child likely has an ear infection.

A 2-year-old girl presents crying with an earache, having slept poorly and received a single dose of acetaminophen during the previous night. While waiting for the doctor, she is given a dose of acetaminophen at the paediatrician's request. The tympanic membrane cannot be visualized due to impacted cerumen. The paediatrician instils 'magic' docusate drops and places a cotton wick 'furry ball' in the external canal. As his patient lies in her mother's lap, she reads some stories and plays a smartphone game with her daughter while he attends to another patient. After 10 min, the medical assistant comes in, explains to the child that her ear is going to have a little bath so the doctor can see better and she gently irrigates the ear. The doctor returns, thanks the child for helping him by being brave and wicks the canal dry revealing an inflamed and retracted, but non-bulging tympanic membrane. He chooses to treat with analgesics alone, explaining around the clock administration of ibuprofen to the parent and presenting her with a written step-up plan based on the addition of acetaminophen. He also prescribes Auralgan® drops in the event pain returns before the next dose of analgesia is due. The parent is given a dose sheet upon which the per-weight ibuprofen and acetaminophen doses appropriate for the child are indicated and circled. A follow-up parental phone report is arranged.

## CHAPTER 34

# Effective management of children's pain and anxiety in the emergency department

Robert M. (Bo) Kennedy

### Summary

Effective management of children's pain and anxiety during emergency department (ED) visits facilitates medically necessary care and procedures and increases patient, family, and health care provider satisfaction. This chapter will review evidence-based techniques for achieving this goal. A significant focus is upon non-pharmacological strategies to relieve children's anxiety because high levels of anxiety exacerbate sensitivity to pain and disrupt coping mechanisms of the child and parent. In addition, advances in techniques for pain relief for specific procedures will be detailed. Aspects of procedural sedation and analgesia that are especially pertinent to the ED will also be reviewed along with two recommended regimens for moderate and deep sedation.

### Introduction

Pain due to injury or illness and fear of painful medical procedures are common experiences for most children seeking care in the ED (Drendel et al., 2006; Zempsky et al., 2004a). Although the truly 'Ouchless ED' (Kennedy and Luhmann, 1999) is more a philosophical concept than a concrete goal, there are many strategies to reduce pain and distress in this setting. Poorly managed pain is distressful for children, their parents, and health care providers and may produce physiological and psychological reactions that have acute and long-term consequences in children of all ages (Pate, 1996; Taddio et al., 1997; von Baeyer et al., 2004; Weisman et al., 1998). Inadequate pain control is also a significant cause of dissatisfaction with emergency care (R. W. Smith et al., 2007). Finally, effective management of children's pain and anxiety facilitates accurate physical exam assessments, performance of necessary medical procedures, and compliance with recommendations.

A child's perception of pain is significantly affected by his emotional state, temperament, prior painful experiences, and coping skills, as well as by parent and health care provider interactions (Khan and Weisman, 2007). Anxiety, exacerbated by the unknown and frightening ED environment, often interferes with a child's and his parent's coping mechanisms. Approaching the child with

a calm, playful style can significantly reduce both the child's and parent's apprehension. Redirecting the child's attention away from his pain and impending medical care can significantly reduce distress. Family members can aid in these distraction strategies but may need specific guidance (Bauchner et al., 1994; see Cohen et al., Chapter 53, this volume).

Most children desire to have their parent present during medical care, even when they know their parent cannot reduce their pain (Ross and Ross, 1984). In addition, most parents wish to be with their child in these situations because they believe they can help reduce their child's distress and be helpful to the health care providers (Bauchner et al., 1989). Allowing young children to assume 'positions of comfort' when feasible, e.g. suggesting the child lay in his parent's lap during suturing or sitting chest-to-chest with the parent giving a gentle but controlling hug during a venous catheter insertion reduces distress in young children and their parents, when local anaesthesia is also used (Sparks et al., 2007).

### Analgesics in the ED

Painful conditions are usually identified when the child is initially triaged upon presentation to the ED. Interventions can be initiated at this time for many patients, including for anticipated painful medical interventions. Placement of topical local anaesthetics which require 30 to 60 min absorption time to be effective also can improve efficiency of care. Examples include instillation of lidocaine-epinephrine (adrenaline)-tetracaine (LET) gel into lacerations (Priestley et al., 2003) or application of anaesthetic skin creams on a child who is likely to require venous cannulation. When a fracture is suspected, splinting the injury and administering oral oxycodone at triage prior to sending the child for radiographs safely reduces the child's pain, including during manipulation of the injured extremity for the radiographs (Charney et al., 2008). Rapid initiation of pain relief for other painful conditions such as burns or sickle-cell vaso-occlusive episodes can also be achieved with administration of oxycodone at triage. Standing orders for nurse initiation of these strategies greatly facilitates this practice.

Acetaminophen (paracetamol) and ibuprofen are frequently used oral analgesic medications for mild to moderate pain, whereas ketorolac and opioids are commonly administered intravenously (IV) for more severe pain. Because some people poorly metabolize codeine to its active form and others experience increased adverse effects from relatively small doses when they ultra-rapidly metabolize the drug, codeine is considered an unreliable analgesic agent (Gasche et al., 2004; Williams et al., 2002). Oxycodone is an effective and safe oral analgesic for significant pain (Charney et al., 2008).

*Acetaminophen (paracetamol)* is administered at 10 to 15 mg/kg/dose orally every 4 to 6 h, not to exceed five doses in 24 h; maximum daily dose: 4000 mg/day.

*Ibuprofen* is administered orally 75 mg/kg/day not to exceed 3750 mg/day. Administration with food or milk decreases gastrointestinal upset. Ibuprofen 10 mg/kg provided similar reduction in fracture-related pain as oxycodone 0.1 mg/kg (Koller et al., 2007) or acetaminophen with codeine (Friday et al., 2009) and better than acetaminophen or codeine alone (Clark et al., 2007).

*Ketorolac* is usually administered IV for moderate to severely painful conditions such as migraine headache (Brousseau et al., 2004). For children aged 2 to 16 years and those older than 16 years who weigh less than 50 kg, the recommended dose is 0.5 mg/kg as a single dose; maximum dose: 15 mg. For children older than 16 years and greater than 50 kg, the recommended dose is 30 mg.

*Morphine* (0.05–0.1 mg/kg IV) is the mainstay for potent analgesia in the paediatric ED. It reliably provides sustained relief for most painful conditions. However, other medications may have advantages in specific conditions.

*Fentanyl* (1–2 mcg/kg IV), unlike morphine, does not cause clinically significant histamine release and thus is preferred in patients who have increased potential for hypotension, e.g. trauma or sepsis. Its rapid onset facilitates titration to effective analgesia. Intranasal (IN) administration of fentanyl (1.5–2 mcg/kg) has been shown to provide similar analgesia as intravenously administered morphine for fracture-related pain (Borland et al., 2007). It can also be used to augment sedation for painful procedures, e.g. with nitrous oxide (N<sub>2</sub>O) for abscess incision and drainage or fracture reduction (Seith et al., 2012). IN administration is facilitated by devices that create a fine mist to increase broad distribution of the drug onto nasal mucosa (Wolfe, 2007).

*Oxycodone* is an opioid analgesic medication that is readily absorbed by the oral route and is often administered for painful conditions when no IV access is established, e.g. at triage for possible fractures or burns (Charney et al., 2008). It can also be used to augment sedation for painful procedures without vascular access, e.g. with N<sub>2</sub>O. For out-of-hospital analgesia 0.05–0.15 mg/kg is recommended. For ED analgesia, 0.2 mg/kg administered at triage to children with painful injuries caused tiredness but not sedation or clinically apparent changes in ventilation or oxygenation (Charney et al., 2008). For procedural analgesia, 0.2 mg/kg may be administered along with N<sub>2</sub>O for minor fracture reduction, burn debridement, or abscess drainage.

### Local anaesthesia

Effective local anaesthesia greatly reduces anxiety and the need for procedural sedation, particularly when topical and nearly painless placement of anaesthetics can be achieved (Pierluishi and Terndrup,

1989) and behavioural interventions are used (see also Zempsky, Chapter 47, this volume).

Gels containing 4% lidocaine, 0.1% epinephrine (adrenaline), and 0.5% tetracaine (LET), when instilled for at least 30 min into an open wound, are sufficiently absorbed to provide local anaesthesia (Eidelman et al., 2011; G. A. Smith et al., 1997). These gels provide complete anaesthesia for 70% to 90% of facial and scalp lacerations and about half of extremity lacerations (Singer and Stark, 2001; G. A. Smith et al., 1997). Thus, supplemental injected anaesthetic is often necessary. Application of gel formulations directly into the wound is more effective than placement of gauze soaked with anaesthetic solution atop, perhaps due to improved contact of the anaesthetics with the wound (Resch et al., 1998). Because topical anaesthetics can cause toxicity due to rapid absorption when applied on mucosal membranes and large abrasions, only small amounts should be applied on these wounds, e.g. use a cotton swab to apply a drop of LET into a lip laceration (Bonadio, 1996). Application of LET to fingers for 45 min is effective and safe (White et al., 2004).

Numerous studies confirm local anaesthetics significantly reduce the pain of needle puncture during IV catheter insertion, blood sampling, and intramuscular vaccine injections (Schechter et al., 2007; Zempsky, 2008). Topical anaesthetic creams containing lidocaine-prilocaine (EMLA®), tetracaine (amethocaine; Ametop®), or liposomized lidocaine (L.M.X.<sub>4</sub>®) reduce venepuncture pain but require 30 to 90 min for penetration (Eidelman et al., 2005). A topical patch uses warming to hasten onset of topical anaesthesia (Synera®; Sethna et al., 2005). These anaesthetics may be applied in triage when it is clear the child will need venepuncture or IV insertion.

Buffering lidocaine, lidocaine with adrenaline, or bupivacaine to a neutral pH significantly reduces the pain of infiltration without impacting effectiveness (Christoph et al., 1988; McKay et al., 1987). Adding 1 ml of sodium bicarbonate (8.4%) per 10 ml of anaesthetic brings the pH of the solution to 7.2 to 7.4. Because buffered lidocaine begins to degrade after 2 to 4 weeks, it must be mixed locally or purchased from specialty pharmaceutical companies. To assure effective local anaesthesia in lacerations, consider injecting buffered lidocaine through the wound after 30 to 45 min of application of LET (see Box 34.1). Buffered lidocaine can be injected through a 30-gauge needle with minimal pain and achieves immediate deep local anaesthesia for IV catheter insertion (Klein et al., 1995; Luhmann et al., 2004; McNaughton et al., 2009). Because of the rapid onset and effectiveness of anaesthesia, lack of need for special equipment and low cost, this technique is used for more than 85% of IV insertions in children in the author's ED (unpublished data). Of note, use of local anaesthetics has been found by some to improve success rate on the first attempt (74% with 4% lidocaine cream versus 55% for placebo; Taddio et al., 2005) and 84% with EMLA versus 65% with nothing (Baxter et al., 2005). The J-tip® device can be used to drive lidocaine through intact skin without use of a needle (Jimenez et al., 2006).

### Pain management for ED procedures

Procedures commonly performed in the ED that are considered intensely painful by paediatric ED health care providers, with most painful first, are suprapubic aspiration, intramuscular injection, lumbar puncture, IV catheter insertion, urethral catheterization,

**Box 34.1** Methods to minimize pain of local anaesthesia (LA) injection

1. Distract patient.
2. Use topical anaesthetic gel prior to infiltration of additional LA.
3. Warm LA to body temperature.
4. Buffer LA to neutral pH (add 1 ml of 8.4% sodium bicarbonate to 9 ml of anaesthetic).
5. Use fine needle (27–30 gauge).
6. Inject slowly.
7. Use smallest effective volume.
8. Infiltrate through wound, not skin.
9. Inject 'looser', deeper subdermal layer before 'tighter' dermal tissues.
10. Block individual nerves when possible.

and nasogastric (NG) tube insertion (Babl et al., 2008a). Effective pain management or alternative procedures can be achieved for most of these procedures. Ceftriaxone can be reconstituted with buffered lidocaine to reduce injection pain when that antibiotic is administered by the intramuscular route (Hayward et al., 1996). Strategies for the remaining procedures are addressed in the following sections.

### Venous access

Venepuncture to obtain blood samples for medical tests or to insert indwelling catheters is the most common painful procedure performed in the ED (see also Taddio, Chapter 19; Zempsky, Chapter 47, this volume). Needle-sticks cause significant pain, distress, and negative memories for children of all ages (Humphrey et al., 1992). Among medical procedures during hospital encounters, needle-sticks are a separate, critical, and distressful event for most children (Fradet et al., 1990). Despite guidelines and increasing evidence highlighting the importance of pain associated with venous access procedures, management of this pain is often inadequate (Bhargava and Young, 2007; MacLean et al., 2007; Zempsky et al., 2004a).

Increasing evidence suggests infants experience needle-stick pain more intensely than older children (Anand and Scalzo, 2000; Kennedy et al., 2008). Furthermore, increased distress during needle-sticks, including in newborns and older infants (Peters et al., 2003; Taddio et al., 2002), has been associated with negative memory and greater distress during future procedures and avoidance of future medical care (Davey, 1989; Pate, 1996; von Baeyer et al., 2004).

Poorly managed venous access pain also impacts the child's family members. Increases in heart rate, blood pressure, and anxiety have been measured in parents who observed their child receiving a venepuncture in the ED (R. W. Smith et al., 2007). In a prospective ED survey of parents of children younger than

8 years of age, 65% were willing to stay an extra hour, 77% were willing to spend an extra \$15, and 37% were willing to pay an extra \$100 to ensure that the procedure was painless (Walsh and Bartfield, 2006).

Health care providers find performing venous access procedures in fearful and anxious children to be stressful. The morale of nurses has been negatively impacted by perceptions that they cause significant procedural pain (Nagy, 1998). Nurses in our paediatric ED reported a significant reduction in their distress associated with IV insertion after they began using comfort techniques and a protocol that empowered them to initiate use of local anaesthesia (Luhmann et al., 1999).

Even with complete anaesthesia (see 'Local anaesthetics'), anxiety related to needle use causes distress in many kids, thus local anaesthetic techniques are considerably augmented by concurrent use of non-pharmacological techniques to reduce anxiety. In addition to distraction simply allowing young children to sit upright on their parent's lap during IV insertion, instead of being held supine on a stretcher, can significantly lower distress, increase parent satisfaction, and does not alter the number of IV attempts needed (Sparks et al., 2007).

### Lacerations

Children presenting to the ED for care of lacerations are typically frightened and anxious. These moderately painful injuries cause concern in the patients and their parents about additional pain during repair as well as cosmetic and functional outcomes. As previously discussed application of topical anaesthetic gels and use of oxycodone at the time of triage immediately begins to address the child's pain and can improve efficiency of care (Charney et al., 2008; Priestley et al., 2003). Use of injected anaesthetics is discussed in the 'Analgesics in the ED' section.

Many small lacerations may not need to be closed. In an intriguing study, patients (primarily adults) with uncomplicated lacerations of the hand that would normally be sutured (full thickness, <2 cm, without tendon, joint, fracture, or nerve complications), were randomized to either being sutured or conservative treatment (tap water irrigation, antibiotic ointment, and gauze dressing for 1–2 days; Quinn et al., 2002). Both groups had similar time to resumption of normal activities and cosmetic appearance with the conservative treatment faster and less painful. In the author's ED most parents quickly accept the advantages of this 'common-sense' approach for minor hand/finger and foot/toe lacerations when reminded of how they likely treated their own similar minor injuries. Although initially worrisome in appearance, tongue lacerations very rarely need closure, including gaping lacerations extending to the tongue's edge (Patel, 2008).

Surface skin adhesives (octyl- or butyl-cyanoacrylates) and adhesive-strips have been used for many years to close clean minor wounds in areas where there is little tension or motion (Farion et al., 2003; Zempsky et al., 2004b). Cosmetic outcomes have been similar to closures with sutures and with reduced procedure pain and time. Careful approximation of irregular wound edges during gluing can be challenging in restless children, but a newly evaluated adhesive mesh used for initial approximation may make this easier and a stronger closure (Singer et al., 2011). Staples, while enabling rapid closure of wounds, require special tools and a return visit to health care for removal, making this a less desirable technique than absorbable sutures, glue, or adhesive strips.

Use of absorbable sutures obviates the need for a second distressful health care visit for suture removal. Suture materials that degrade significantly by 3 to 10 days, e.g. 6–0 fast-absorbing or plain gut or irradiated 5–0 polyglactin 910 (Vicryl Rapide™), are used for facial laceration closure with similar cosmetic outcomes to closure with nylon (Al-Abdullah et al., 2007; Karounis et al., 2004; Luck et al., 2008). Slightly longer lasting materials, e.g. 4–0 chromic gut or Vicryl Rapide™ are used for closure of trunk or extremity lacerations. As an adjunct, the tissue adhesives may be used to cover, protect and reinforce fragile rapidly absorbed gut sutures, thus allowing children to shower.

### Lumbar puncture

Lumbar puncture (LP) is commonly performed in infants and toddlers without local anaesthesia or other pain management, despite this being the standard in older children and adults. A 2004 survey found two-thirds of academic paediatric emergency physicians do not routinely use local anaesthesia for neonatal LPs (Baxter et al., 2004). In a 2007 survey of paediatric and emergency medicine residents across Canada, paediatric residents reported performing LPs with no local anaesthetic much more frequently than their emergency medicine counterparts (Breakey et al., 2007). Slightly more encouraging, a 2011 prospective study found that local anaesthetics were administered in 54% of infants less than 12 months of age and in 99% of toddlers 12 to 24 months of age undergoing LP for suspected meningitis in the ED or paediatric units at a university hospital (Gorchynski and McLaughlin, 2011). Emergency physicians exclusively used injected 1% lidocaine while paediatric physicians preferred a topical anaesthetic. However, a 2011 survey of ED faculty and paediatric emergency medicine fellows at five Midwestern US hospitals, with approximately half of respondents trained in general emergency medicine, found that although 78% of the physicians believed pain intervention is worthwhile for infant LPs, less than one-third regularly use pharmacological interventions to reduce LP pain in this age group (Hoyle et al., 2011).

There is a surprising lack of literature on the effectiveness of local anaesthesia in reducing the pain of LP in neonates (Madsen, 2009). In a randomized double-blind comparison of the topical anaesthetic cream EMLA® to placebo cream in newborns undergoing LP, all the newborns had evidence of pain (Pinheiro et al., 1993). However, compared with placebo, EMLA® significantly attenuated the pain response as shown by lower heart rates and behavioural scores. This and other studies demonstrate that infants typically cry and struggle when simply positioned for a LP, whether or not topical or injected local anaesthesia is used, and that reduction in distress associated with use of a local anaesthetic may be difficult to discern clinically (Porter et al., 1991). Administration of oral sucrose and use of non-nutritive sucking, in addition to local anaesthetic, provides additional reduction of distress.

Common rationales for not using injected lidocaine in infants include that its use makes the infant suffer 'two sticks instead of one' and that the injected lidocaine makes the LP more difficult by obscuring landmarks. However, a 1993 study of neonates undergoing LP found that while the infants struggled when infiltrated with lidocaine, those who received lidocaine struggled significantly less during the spinal needle insertion (Pinheiro et al., 1993). Consistent with these findings, a 2006 prospective observational study of infants in a university ED found LPs performed with local anaesthetic were twice as likely to be successful and

atraumatic (Baxter et al., 2006). Finally, a 2007 prospective evaluation of 1459 children, median age of 3 months, who were undergoing LPs in a single ED, found that not using a local anaesthetic was a significant independent predictor of traumatic or unsuccessful LP on the first attempt (35%; Nigrovic et al., 2007). These studies suggest use of local anaesthetics in infants reduces distress and struggling and increases the likelihood of a successful atraumatic LP.

What is the most effective local anaesthetic technique in older children also remains an open question. No clinical trials of local anaesthesia were found in non-infant children undergoing LP in the ED. Reduction of pain with EMLA® prior to lumbar puncture has been found in children with cancer when the LP was successful on first but not subsequent attempts (Holdsworth et al., 1997). Double-blinded randomized trials in older children undergoing LP in the ED are needed to evaluate the effectiveness of newer options such as buffered lidocaine, injection with 30-gauge needles, and liposomal lidocaine cream.

Many children benefit from sedation during elective LP but children undergoing LP in the ED are often ill and may have compromised cardiopulmonary function, worsened by being held in a maximally flexed position for the procedure, thus increasing the risk of adverse events associated with procedural sedation. For these patients, administration of an anxiolytic dose of midazolam or 50% N<sub>2</sub>O may improve patient tolerance of the procedure with minimal sedation and lessen the likelihood of respiratory depression. This strategy may also make children more amenable to distraction. Effective local anaesthesia is crucial to this strategy.

Recommendations for ED patients undergoing LP are as follows:

*Infants:* anaesthetic cream (e.g. EMLA®, LMX®, Ametop®) followed by slow injection of buffered lidocaine via 30-gauge needle, along with nutritive suckling (pacifier, with sucrose for <6 weeks of age).

*Toddlers and older children:* anxiolysis with midazolam (IV, PO, IN) along with topical anaesthetic cream (e.g. EMLA®, LMX®, Ametop®), distraction by Child Life Specialist or instructed family member or ED staff, slow injection of buffered lidocaine via 30-gauge needle. If N<sub>2</sub>O is available, may substitute or combine with midazolam, monitoring oxygenation with pulse oximetry. If child is very distressed and has good cardiopulmonary function, may consider moderate or deep sedation.

### Urethral catheterization

Urethral catheterization (UC) is considered by children and adults to be one of the most painful and distressing common procedures performed in the ED, with males reporting more pain than females (Babl et al., 2008a; Kozer et al., 2006; Singer et al., 1998). Lubricating anaesthetic gel is widely recommended in adults to reduce the pain caused by the friction and pressure from the catheter's passage through the urethra into the bladder, but this adjunct is rarely used in paediatric ED patients, perhaps due to time constraints and because of only moderate reduction of distress (MacLean et al., 2007; Vaughan et al., 2005).

UC has been found in infants to cause less pain and be more likely successful in obtaining urine for analysis and culture, compared to suprapubic aspiration, without increased adverse events (Pollack et al., 1994; Tobiansky and Evans, 1998). In a study of

febrile full-term infants, less than 2 months of age, suprapubic aspiration through skin anaesthetized by EMLA® was also found to be more painful than UC using a 5-French feeding tube lubricated with sterile 2% lidocaine gel (Kozar et al., 2006).

In older infants and toddlers, behavioural pain scores were high and did not differ during UC in children less than 2 years of age when 1 to 2 ml of either non-anaesthetic or 2% lidocaine gel was applied topically to the genital mucosa for 2 to 3 min before catheterization and the remainder of the gel used as lubricant on the catheter (Vaughan et al., 2005). However, others found reduced distress when 2% lidocaine gel was applied topically for 2 min then instilled into the urethra for 2 more minutes when compared to non-anaesthetic gel in febrile 2- to 24-month-old ED patients (Mularoni et al., 2009).

In children between 4 and 11 years of age, use of 2% lidocaine gel was associated with significantly less pain and distress during UC for cystograms compared to non-anaesthetic gel when the lidocaine gel was applied with sufficient time to provide anaesthesia (Gerard et al., 2003). A cotton ball soaked with either lidocaine or placebo lubricant was placed on the urethral meatus and held in place for 1 to 2 min. Then, dependent upon the size of the child, 0.5 to 2.0 ml lubricant or lidocaine gel was instilled into the urethra. The instillation was repeated twice more, with 2 min intervals between each instillation. A child life specialist provided distraction and support during the procedure and rated the child's distress. The group receiving 2% lidocaine gel had significantly lower self-report pain and observed distress.

Because significant pain and distress occurs with UC despite use of anaesthetic gel, alternative adjuncts have been investigated. Oral *sucrose* solution (24%) administered 2 min prior to UC reduced pain scores and crying in infants less than but not older than 30 days of age (Rogers et al., 2006). Midazolam 0.6 mg/kg orally induced complete amnesia for UC in 60% and partial amnesia in 31% of very anxious children (mean age 4.4 years; Elder and Longenecker, 1995) and intranasal midazolam 0.2 mg/kg significantly reduced distress in children median age 2 to 3 years (Stokland, 2003). Intranasal fentanyl, 2 mcg/kg, of note, did not reduce UC pain in children 4 to 8 years of age (Chung et al., 2010). Most successfully, N<sub>2</sub>O 50% to 70% has been found to reduce distress behaviour and need for restraint in children during UC compared to non-sedated controls or to those receiving oral midazolam (Keidan et al., 2005; Zier, 2007).

### Nasogastric intubation

Although emergency physicians and nurses acknowledge the marked discomfort, NG tube insertion is typically performed without any form of pain relief other than a lubricant in children (Juhl et al., 2005; Stock et al., 2008). Studies in adults designed to find an effective local anaesthetic technique for NG tube insertion have primarily focused upon use of 2% to 10% lidocaine as a gel, nasal spray, or nebulized mist (Gallagher, 2004; Kuo et al., 2010). Cetacaine and cocaine have also been investigated but are not recommended due to associated toxicities (US Food and Drug Administration, 2011). A systematic review of five randomized controlled trials in adults concluded that administration of nebulized or atomized lidocaine before NG tube insertion can decrease pain by 60% (Kuo et al., 2010). Two more recent randomized controlled trials in adults likewise found benefit from lidocaine spray (Chan and Lau, 2010) and gel (Uri et al., 2011).

In contrast to the studies in adults, Babl and colleagues, in a well-designed comparison of nebulized 2% lidocaine at 4 mg/kg to saline placebo in children between 1 to 5 years of age in the ED, found distress scores were very high in both groups during NG tube insertion and terminated the study early (Babl et al., 2009). No child demonstrated any evidence of lidocaine toxicity but, of note, the trachea was inadvertently intubated in one child in each group, emphasizing the need for confirmation of gastric placement by pH, radiograph, or other means (Kuo et al., 2010). Further investigations in children are needed to determine how best to reduce the pain of NG tube insertion. Perhaps as important, clinicians may reconsider whether NG tube insertion can be avoided (Witting, 2007).

When considering the available evidence, it is recommended clinicians administer intranasal 2% lidocaine at 4 mg/kg (0.2 ml/kg of 2%) as a gel or atomized spray to children at least 5 min prior to NG tube insertion. Oxymetazoline or phenylephrine nasal sprays may be co-administered to shrink the nasal mucosa and reduce epistaxis. Most children will show signs of distress during the administration of the lidocaine and NG tube insertion but it is likely a significant portion of the pain of the procedure will have been abated. Blunting of protective airway reflexes may occur with these techniques.

### Abdominal pain

Abdominal pain is a common nonspecific complaint in children seeking medical evaluation in the ED (Reynolds and Jaffe, 1992; Scholer et al., 1996). Acute cramping abdominal pain from self-limited minor illnesses such as gastroenteritis or viral infections is not effectively reduced by analgesic medications and may be prolonged by opioids that exacerbate intestinal ileus. Many systemic illnesses may cause abdominal pain, including diabetic ketoacidosis, haemolytic uremic syndrome, Henoch-Schönlein purpura, hepatitis, and myocarditis, the diagnosis of which are usually made with a careful history and physical exam, and, occasionally, specific ancillary tests. Some causes of abdominal pain may require antibiotic treatment including lower lobe pneumonias, urinary tract infections, streptococcal pharyngitis, and pelvic inflammatory disease. It is also important to evaluate for conditions that may require urgent surgical intervention such as trauma, volvulus, intussusception, ovarian torsion, incarcerated hernia, or appendicitis. For many of these conditions, administration of an analgesic medication after a diagnosis or further evaluation or therapeutic intervention is begun will provide some patient relief without obscuring the diagnosis or increasing management errors (Ranji et al., 2006). The best studied example is when the diagnosis of appendicitis is being considered, administration of morphine or buccal oxycodone has been found not to interfere with clinical diagnosis while reducing pain preoperatively and facilitates diagnostic techniques such as abdominal ultrasound (Sharwood and Babl, 2009). However, this practice is frequently underutilized (Goldman et al., 2006; Kim et al., 2003).

### Headache

Headache is a common chief complaint in children presenting to the ED (Burton et al., 1997; Kan et al., 2000; Lewis and Qureshi, 2000). The majority of these children are diagnosed with viral illnesses or migraine headaches. After viral infections, rebound headaches from chronic daily use of ibuprofen or acetaminophen (Vasconcellos et al., 1998), and rare but life-threatening causes of headache, including meningitis, encephalitis, intracranial abscess

or haemorrhage, hydrocephalus, hypertension, or brain tumour are excluded by a careful history, neurological exam, and, if necessary, intracranial imaging (Kan et al., 2000; King, 2012), the diagnosis of migraine headache should be considered (Lewis, 2009). Migraine headaches in children are defined as recurrent headaches with pain-free intervals and at least three of the following six symptoms: (1) an aura; (2) unilateral location; (3) throbbing or pulsatile pain; (4) nausea, vomiting, or abdominal pain; (5) relief after sleep; and (6) a family history of migraines (Lewis, 2009; Prenskey and Sommer, 1979).

Pharmacological treatment of migraine headaches in children in the emergency setting is primarily based upon trials in adults due to few paediatric studies (Lewis et al., 2004). As with other painful conditions, the therapeutic goal is reduction in pain, nausea, and other symptoms to a level which the patient can tolerate; complete abolition of symptoms is uncommon. If the patient has not already taken an effective dose prior to ED presentation, an oral dose of ibuprofen, 10 to 15 mg/kg, or acetaminophen 15 mg/kg may provide relief (Damen et al., 2005; Lewis et al., 2004). Triptans, although not formally approved for use in children, have been shown to reduce migraine-related pain in this age group with benefit best demonstrated in use of nasal sumatriptan 10 to 20 mg (Damen et al., 2005; Eiland, 2010; Lewis et al., 2004). Because triptans induce vasoconstriction, their use with basilar artery and hemiplegic migraine may worsen symptoms.

The combination of intravenous hydration, ketorolac, and prochlorperazine may be an effective treatment for paediatric migraine headaches (Damen et al., 2005; Lewis et al., 2004). A randomized double-blind trial in 62 children aged 5 to 18 years presenting to the ED with a migraine headache compared IV ketorolac (0.5 mg/kg; maximum 30 mg) to prochlorperazine (0.15 mg/kg; maximum 10 mg), after normal saline 10 ml/kg infused over 30 min (Brousseau et al., 2004). By 60 min, 55% of those who received ketorolac and 85% of those who received prochlorperazine had a 50% or greater reduction in pain scores; neither group experienced significant adverse effects. Unfortunately, IV preparations of prochlorperazine are in short-supply or unavailable in the US. Alternative antiemetics that may be effective but little studied include promethazine, chlorpromazine, metoclopramide, and ondansetron.

### Paediatric procedural sedation and analgesia (PSA) in the ED

When effective local anaesthesia is not possible for intensely painful ED procedures or when distress-related behaviours will interfere with accomplishment of the procedure, sedation may be necessary. Many advances in PSA for non-elective procedures in non-fasted children in the ED have been developed (Kennedy, 2011). This section will review aspects especially pertinent to paediatric PSA in the ED (see also Cravero, Chapter 20, this volume).

PSA in children receiving emergency care has greater inherent risks than elective sedation. Patients frequently have not fasted and thus may have 'full stomachs' (Agrawal et al., 2003; Babl et al., 2005; Roback et al., 2004). More importantly, gastric emptying unpredictably may slow or stop due to ileus caused by painful injury or serious illness and is delayed further by opioids administered for pain management. Thus, brief postponement of sedation may have little impact. Compounding this issue, children undergoing painful or anxiety provoking procedures typically require deeper levels of sedation than adults or teenagers to control their behaviour.

Furthermore, unanticipated arrival or deterioration of other critical ED patients may demand sedating team members' immediate attention. These possibilities impact ED PSA choices.

Goals of ED PSA are the same as for elective PSA, with the foremost being assurance of the patient's safety and welfare during sedation and recovery. Aspects with particular pertinence to ED PSA include:

- (1) Most children undergoing ED PSA are ASA Physical Status Class I and II and at low risk for serious adverse events when closely monitored and simple rescue interventions quickly applied (Green et al., 200; Peña and Krauss, 1999). However, children with acute illnesses may have less cardiopulmonary reserve and more likely to have adverse responses to sedative and analgesic medications, but perhaps less so when ketamine is used (Green et al., 2009). A focused physical exam immediately prior to sedation should be repeated to detect any changes in the child's physiological status such as acute onset of wheezing or fever which may increase risk for adverse events.
- (2) Fasting is a well-established consensus-based practice to reduce aspiration risk during elective general anaesthesia. However, little clinical data has been published to help determine risk of adverse events when children undergoing ED PSA have not fasted or whether postponing PSA for a short period reduces risk (Green et al., 2007; Mace et al., 2008). Protective airway reflexes are generally preserved during moderate sedation (American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-Anesthesiologists, 2002) and relatively intact during deep sedation or even light general anaesthesia with ketamine, the most commonly used drug for ED PSA in children (Green et al., 2011). However, these reflexes are likely blunted during deep sedation with opioids, benzodiazepines, barbiturates, and propofol, especially during periods of apnoea (American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-Anesthesiologists, 2002; Oberer et al., 2005). Intubation of the trachea, rarely performed for ED PSA, likely increases the risk of pulmonary aspiration due to pharmacological abolition of protective reflexes to facilitate intubation and mechanical interference with glottis closure during passage of the endotracheal tube; thus elective intubation for ED PSA may increase risk of aspiration. Routine administration of antacids or pharmacological agents to increase gastric motility prior to general anaesthesia is not beneficial (American Society of Anesthesiologist Task Force on Preoperative Fasting, 1999); this likely holds true for ED PSA.

The incidence of pulmonary aspiration during ED PSA is not well established but appears to be very low. Pooling of the available data in the literature suggests the incidence of clinically apparent pulmonary aspiration during ED PSA is no more frequent than 1:2000 paediatric patient encounters (Mace et al., 2008).

Vomiting, usually during recovery, is a common adverse event during ED PSA in children, occurring in as much as 25% of patients when opioids are co-administered prior to sedation (Luhmann et al., 2006; Wathen et al., 2000). No correlation was found between the length of preprocedural fasting and vomiting in children receiving ketamine or N<sub>2</sub>O (Agrawal et al., 2003; Babl et al., 2005; Roback et al., 2004). Coadministration of ondansetron reduced vomiting associated with ketamine ED PSA from 12.6% to 4.7% with 13 patients needing to be treated to prevent one episode of vomiting

(Langston et al., 2008). Fortunately, protective airway reflexes are likely present during active vomiting. Passive regurgitation of gastric contents due to relaxed gastro-oesophageal sphincter tone, e.g. during apnoea, however, may be associated with pulmonary aspiration.

When local anaesthesia or effective analgesia can be achieved, safety may be enhanced and some children may prefer lighter levels of sedation without loss of awareness, e.g. N<sub>2</sub>O with a fracture haematoma block.

In many smaller EDs, the only physician present must be responsible for performing both the sedation and the procedure. In these situations, there must be a second staff member at the bedside who has been trained in sedation and resuscitation techniques. This second person is responsible for monitoring the patient's cardiopulmonary status and the need for interventions to manage adverse events. This individual may, for moderate sedation, assist with minor, interruptible tasks once the patient's level of sedation and cardiopulmonary functions have stabilized, provided adequate monitoring of the patient is maintained (American Academy of Pediatrics Committee on Drugs, 1992; American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-Anesthesiologists, 2002; Godwin et al., 2005). For deep sedation, this second staff member should have no other responsibilities than monitoring the patient and recording. This usually means a third provider is needed if assistance in performing the procedure is expected. The responsible physician must be able to easily interrupt performance of the procedure to assist with or assume management of adverse events.

#### ED PSA technique recommendations for children

Many PSA techniques for ED paediatric procedures have been reported (Kennedy, 2011). It is recommended that the provider become knowledgeable and experienced with a limited number when initially gaining experience with paediatric ED PSA. Use of N<sub>2</sub>O or ketamine enables safe and effective ED PSA in children for most ED procedures. Techniques that have greater frequency of adverse cardiopulmonary effects, e.g. fentanyl + propofol or midazolam, should be used only by experienced sedation providers.

N<sub>2</sub>O 50% to 70% induces mild to moderate sedation with anxiolysis, moderate analgesia, and partial amnesia. Its advantages include no need for venous access, rapid onset and offset (within 2–5 min), and few adverse effects other than vomiting or occasional dysphoria. Delivery of the gas via full face mask rather than a dental-style nasal hood is more effective for ED PSA. Deeper sedation can be achieved by co-administration of opioids with N<sub>2</sub>O but the risk of adverse effects, especially vomiting, is increased (Luhmann et al., 2006; Seith et al., 2012).

At a specific concentration of N<sub>2</sub>O, depth of sedation can vary considerably. Babl found 90% of children receiving 50% to 70% N<sub>2</sub>O were mildly sedated, whereas moderate or deep sedation occurred in 3% receiving 70% N<sub>2</sub>O and in none receiving 50% (Babl et al., 2008b). When administered along with IN fentanyl or oral oxycodone, 50% N<sub>2</sub>O induced deep sedation in 15% to 20% (Luhmann et al., 2006; Seith et al., 2012). As much as 10% of children may be poorly sedated during ED PSA with N<sub>2</sub>O (Babl 2008b, 2008c; Luhmann et al., 2001). Augmentation of N<sub>2</sub>O analgesic effects by concurrent use of local anaesthesia and/or systemic analgesia for painful procedures is also crucial (Babl et al., 2008c). Since children are partially aware during N<sub>2</sub>O sedation, strategies to enhance the gas's anxiolytic, dissociative, and euphoric effects are vital to

successful use. Guided imagery significantly augments N<sub>2</sub>O's efficacy and helps allay anxiety. Children naïve to intoxication are frequently frightened by the floating or tingling sensations caused by the gas, but they usually accept these effects when incorporated into non-frightening story-telling (Clark and Brunick, 2007b; Clark et al., 2006). N<sub>2</sub>O can safely be administered by specially trained nurses to healthy children for ED PSA (Frampton et al., 2003).

N<sub>2</sub>O is effective for brief painful ED procedures, especially when local anaesthesia is used—examples include lacerations, lumbar puncture, IV placement, urethral catheterization, and abscess incision and drainage (Babl et al., 2008b; Keidan et al., 2003; Luhmann et al., 2001). Oxycodone 0.2 mg/kg PO (or fentanyl IN 2 mcg/kg) provides additional analgesia in young children with injuries that are difficult to fully locally anaesthetize and may result in deep sedation (Seith et al., 2012).

For displaced mid to distal forearm fractures, a combination of N<sub>2</sub>O + oxycodone or intranasal fentanyl + lidocaine haematoma block reduces patient distress as effectively as ketamine, avoids need for venous access, and results in rapid recovery (Luhmann et al., 2006). An effective haematoma block (2.5 mg/kg, maximum 100 mg buffered 1% lidocaine) is critical for this technique. For simple greenstick fractures, the haematoma block is less reliable but significant analgesia is provided and residual pain during reduction is often ameliorated by partial amnesia (Hennrikus et al., 1995).

Ketamine induces dissociative deep sedation or light general anaesthesia within 60 sec of IV administration with little significant respiratory depression or blunting of protective airway reflexes and causes a mild increase in heart rate and blood pressure (Green et al., 2011). It more effectively reduces pain and distress and causes less adverse cardiopulmonary effects than regimens using fentanyl with midazolam or propofol (Godambe et al., 2003; Kennedy et al., 1998). Because of these attributes, ketamine is the most widely used technique for ED PSA in children. Nonetheless, respiratory depression or apnoea, usually brief, may rarely occur (Green et al., 2009). Complete lack of responsiveness to painful stimuli is unnecessary with ketamine as it is also a potent amnestic agent (Kennedy et al., 1998).

Laryngospasm has been reported to occur in as many as 0.3% of children undergoing ketamine PSA, often during recovery (Green et al., 2009). Providers must be prepared to manage laryngospasm by initiating continuous positive airway pressure along with jaw thrust-head tilt to open the airway. These interventions likely will be sufficient, but if obstruction persists, succinylcholine (0.1–1 mg/kg IV) may be required to break the laryngospasm (Hampson-Evans et al., 2008). Most laryngospasm will be brief but relapses have been reported (Cohen and Krauss, 2006). Febrile upper respiratory infections may increase risk for laryngospasm (Olsson and Hallen, 1984).

## Conclusion

Pain assessment and management in the ED is a vital component of care. Sometimes that involves systemic analgesia, sometimes local anaesthesia, sometimes distraction, sometimes sedation, but often, all of these. Effective management of pain and distress improves patient outcomes by protecting the children psychologically and physiologically, and by enabling us to perform more accurate examinations and necessary painful therapeutic and diagnostic procedures. Furthermore, it improves health care provider credibility, parental satisfaction, and compliance with recommendations. In this evidence-based review, proven techniques to achieve these

goals have been highlighted and areas where further research is needed to develop improved safe and effective methods have been identified.

### Case example

A 3-year-old boy sustained a gaping 3 cm laceration to his forehead when he fell on the playground. Topical anaesthetic LET gel has been applied during triage. He is fearful and resists your exam. His mother thinks he will not be still during suturing. You consider sedation with ketamine but wonder whether there are alternatives that will require less time and fewer ED resources. The following strategies are suggested.

This child has been frightened by his injury and is worried that the treating ED staff, strangers to him, will cause additional pain during repair. Several techniques may help him feel less threatened by refocusing his attention away from his injury. First, chat in a relaxed manner with his parent. One then might play a brief game with younger patients, e.g. offering a palm-up 'give me five' hand-slap greeting but quickly move the hand when the child tries to give the slap, causing him to miss. Surprised by a doctor playing a familiar game, many children break into a smile, as do their parents. Alternatively, initially asking the child about her shoes, toy, or some object other than their injury, helps many relax by transferring their attention to something familiar and non-frightening. Likewise, when preparing to suture, one may ask the young child to tell about his last birthday party, colour a picture, recite the 'ABCs' or sing a favourite bedtime lullaby. Playing an interactive game on a computer tablet can be an extremely effective distraction. Family members can aid in these distraction strategies but may benefit from specific guidance. Suturing as the young child sits in his parent's lap can be very reassuring. With school-aged or teenage children, a simple joke, e.g. 'So, your sister/brother/girlfriend, etc, had nothing to do with this (injury), right?' may help them relax. Getting the child and parent to laugh usually eases their tension.

In addition, effective painless local anaesthesia is critical. Instil LET gel directly into the wound and cover for at least 30 min. Application of LET at the time of triage provides time for absorption and immediately addresses the child's pain. If time permits, returning several times to the child's treatment room to re-apply the LET without causing pain helps desensitize the anxious child to one's presence and to manipulation of his wound. Because complete anaesthesia may not be achieved with LET, especially in non-facial lacerations, augment the local anaesthesia by injecting buffered lidocaine using a short very fine needle, e.g. ½ inch 30 gauge. Show the child the syringe without the needle, tell him you will put some medicine into his 'owie' (the wound), that 'it might feel really cold' and ask him to let you know if you are 'pushing too hard' as you apply the medicine. This helps the child interpret the sensation in a non-frightening manner. Avoid alarming language such as, 'a little stick', 'burning', or 'hurt'. Obscure the syringe and needle by keeping it close to the child's face making it difficult for the child to see the needle. Inject slowly through the wound. Finally, consider administering oral oxycodone, 0.2 mg/kg, to reduce the tenderness of the bruise surrounding the injury; this often also causes children to feel tired and more relaxed. Using these techniques, the need to sedate children for laceration repair can be significantly reduced.

# Measurement of pain

*This page intentionally left blank*

## CHAPTER 35

# Neonatal and infant pain assessment

Grace Y. Lee and Bonnie J. Stevens

### Introduction

Pain assessment in neonates and infants is challenging. Although clinicians and scientists have benefited from impressive increases in research on developmental neurobiology, behaviour, and physiology of infant pain capabilities and responses, there is no 'gold standard' infant pain indicator, measure, or approach. Therefore, pain is inferred from the observed responses. These responses are not easily interpretable as they are: (1) modified by contextual factors (e.g. previous experience with pain) and individual infant characteristics (e.g. gestational age (GA), postnatal age (PNA), gender, health status); (2) dependent on the attitudes, beliefs, knowledge, and observational skills of care providers; and (3) reliant on the availability of psychometrically sound assessment measures. Inferring pain is not unique to infants; in adults, for example, self-report is not a direct unbiased measure of this subjective phenomenon—rather it is influenced by a multiplicity of factors and is thus, an indirect measure. In fact, some would suggest that no direct measure of pain has been validated to date.

Pain assessment is an essential foundation for instituting pain relieving interventions to mitigate pain and its consequences in the developing child. Effective pain management is frequently considered an indicator of quality health care practice (Sidani, 2003). Therefore, accurate, timely and feasible pain assessment needs to be featured in policies, guidelines, and procedures at the institutional and policy implementation levels. However, the measurement of pain in neonates and infants may be imprecise and inadequate. This dilemma begs the question as to whether it is possible to develop the perfect measure for this population. In the meantime, we advocate using the best measures available while addressing the existing measurement issues.

This chapter encompasses: (1) the conceptualization of infant pain within a particular biopsychosocial and developmental context; (2) a comprehensive evaluation of existing neonatal/infant pain assessment measures and indicators (e.g. biomarkers and cortical indicators); (3) integration of recommendations on pain assessment measures and practices within clinical practice guidelines, policies, and procedures; and (4) challenges associated with neonatal and infant pain assessment in terms of research, clinical and knowledge translation (KT) issues.

### Conceptualization of pain in neonates and infants

#### Pain and nociception

Pain is an elusive phenomenon that poses unique measurement challenges. For adults, pain measurement usually encompasses the verbal response of the individual experiencing it. However, the inability to communicate verbally does not preclude the individual from pain or negate their need for pain-relieving treatment; thus, behavioural and physiological indicators are commonly used as proxies in assessing pain in infants. However, due to the infant's developmental stage and associated vulnerability, they are completely dependent on their caregivers to observe and interpret these indicators. Their expression of pain and experience are intrinsically intertwined with the caregiver and the sociocultural context in which pain is experienced.

Pain is often conceptualized within the biomedical model of care where the focus is on the sensory processes of nociception and the transmission of signals originating from peripheral nociceptors to receptors in the brain. This model is limited in understanding pain in infants and is an incomplete representation of pain in humans (Sullivan, 2008). Given the importance attributed to the psychosocial context and the processes of development and interaction with the infant's environment, theories such as the systems-based synactive theory of development (Als, 1982) and the social communication model (SCM) of infant pain (Craig, 2009) are extremely relevant.

#### The synactive theory of development

The synactive theory of development (Als, 1982) focuses on the evolving, continuous, and dynamic relationship between key subsystems within the developing infant organizational structure (e.g. autonomic, motor, state organizational, attentional-interactive, and self-regulatory) and salient aspects of the environment. Als asserts that the infant alternates between stabilizing (e.g. smooth well-regulated functioning) and integrating responses to facilitate functional competence. The caregiver's role is to protect the infant (especially preterm newborns) against external sources of stress and mitigating its effects. The Neonatal Individualized Developmental

Care and Assessment (NIDCAP) programme with a central focus on the social processes involved in protecting and maintaining the stability of the infant within a particular external environment has evolved from this theory. The Assessment of Preterm Infants' Behaviour (APIB) instrument (Als et al., 1982) provides a systematic profile for assessing the individual infant's behavioural cues as a measure of their system capacity and regulatory abilities. Preventing and/or minimizing stressful procedures, assisting the infant to maintain and regulate organized behavioural state and instituting developmentally specific strategies to mitigate the effects of stressful events are hallmark interventions. These physical (e.g. positioning, bundling), tactile (e.g. kangaroo care, non-nutritive sucking), and behavioural (e.g. distraction) strategies are also used as pain-relieving interventions.

### The social communication model of pain

The SCM (Craig, 2009) promotes understanding of the complex interactions between biological, psychological, and social features of pain. Craig asserts that pain is a sequence of complex interdependent stages, characterized by feedback loops among sequential stages. Assessing infant pain is construed as a dynamic, interactive process between child and caregiver (e.g. health professional, family or others) who are uniquely influenced by family, community, and culture. Infants almost invariably react to acute tissue stress and damage in a manner that distinguishes 'pain' from 'non-pain' states. These reactions provide a means for caregivers to decode the pain expression and infer the infant's subjective state from biological and behavioural correlates.

This model is unique in its focus on interaction with the caregiver encompassing their cognitive and affective capabilities that support complex social interactions and processes. Once pain is expressed by the infant, caregivers interpret that the infant is in pain. This attribution of pain is influenced by the caregiver's (1) sensitivities, (2) knowledge level (e.g. of the specific child or alternatives to distress), (3) attitudes and beliefs, and (4) prior relationship to the child. The stage is then set for implementing and evaluating pain-relieving interventions.

While the SCM of infant pain addresses the broader context of pain, our current knowledge is primarily centred on acute tissue-damaging or nociceptive pain, with little clarity on the infant's experience and expression of more prolonged acute (e.g. postoperative), persistent (e.g. recurrent), or chronic pain. This understanding is important as the basis for the development and validation of pain assessment indicators and measures in these domains. A more detailed exploration of the SCM is provided by Pillai Riddell et al. (Chapter 9, this volume).

## Pain assessment measures and indicators

### Acute versus chronic

Neonatal and infant pain assessment measures have been developed for both acute and chronic pain. *Acute pain* signals a specific nociceptive event, injury, or illness, is usually of sudden onset, and is limited to a short period of time. Acute pain typically subsides with effective management after the painful event (e.g. heel lance) or when the illness or injury resolves; it can be persistent and re-occur in multiple episodes over time. Most research on infant pain assessment has used tissue damaging stimuli as the paradigm for

determining behavioural and physiological responses; multidimensional and composite measures are almost exclusively comprised of indicators from acute pain studies. A typical behavioural response depicting the behavioural facial action acute pain response in infants is shown in Figure 35.1.

*Chronic pain* is frequently defined as pain that has persisted beyond the normal tissue healing time. However, the temporal delineation of 'healing time' is debated as somewhere between 3 and 6 months. The temporal delineation presents additional dilemmas when considering prolonged pain in infants. In addition to the issue of total life span, which may be less than 3 or 6 months, infants have limited time comprehension abilities and cannot fully appreciate past, present, and future or process information in a moment by moment fashion. Researchers have largely ignored chronic pain assessment and its complexities in infants focusing almost exclusively on acute pain, with only a few measures addressing this more prolonged phenomenon (see Table 35.1).

### Unidimensional versus multidimensional

Infant pain measures can also be classified as either *unidimensional* (one global item or a multiple items within a single domain) or *multidimensional* (multiple items with multiple domains/composite measures) where *dimension* refers to an aspect of a phenomenon and *domain* is the set of possible dimensions within the phenomenon. Applying these definitions to pain, unidimensional single item measures capture one dimension of the experience (e.g. visual analogue scale capturing pain intensity) whereas unidimensional single domain measures include: (1) multiple items (e.g. brow bulge, eye squeeze) from a single domain (e.g. facial expression) within a single dimension (e.g. behavioural), for example, the Neonatal Facial Coding System (Grunau and Craig 1987); or (2) multiple items (e.g. brow bulge, hand movement, high pitch cry) from multiple domains (e.g. facial expression, movement, cry) within a single dimension (e.g. behavioural), for example, Douleur Aigue du Nouveau-ne (Carbajal et al., 1997).

Multidimensional (composite) measures include multiple items (e.g. brow bulge, heart rate, gestational age) from multiple domains (e.g. facial expression, biomarker,) within multiple dimensions (e.g. behavioural, physiological,), such as the Premature Infant Pain Profile (Stevens et al., 1996). The issue of combining dimensions in multidimensional measures is frequently raised by measurement critics, who suggest mixing poorly correlated dimensions in total scores is unjustified and may lead to ineffective or incomplete management. Conversely, proponents suggest dissociation between indicators is common in a complex entity and therefore taking all dimensions into account is necessary to capture the full scope of the phenomenon for well-informed decision-making (McDowell, 2006).

### Existing neonatal and infant pain measures

Approximately four dozen measures have been developed to assess pain in neonates and infants over the past three decades. Several have been extensively validated, although their feasibility and clinical utility are infrequently addressed. The most well-validated measures are multidimensional behavioural indicators or composite measures. Only a few measures incorporate individual infant characteristics or contextual factors. Furthermore, the current body of neonatal pain measures is comprised of a narrow and finite cadre of behavioural and physiological items. Recommendations to expand this repertoire and to explore potential new indicators

**Figure 35.1** Example of a typical behavioural response depicting the behavioural facial action acute pain response in infants.

(e.g. cortical indices) or biomarkers (e.g. cortisol) and their relationship to observed behavioural indicators have only recently been considered. A critical appraisal of unidimensional and multidimensional neonatal and infant pain measures with demonstrated reliability and validity is summarized in Table 35.1.

### Individual pain indicators

Given the issues associated with observation of behavioural and physiological pain indicators in neonates and infants, researchers have begun to investigate potential biomarkers and neurocognitive/physiological indicators.

#### Biomarkers

Several researchers have conducted studies examining the use of cortisol as a biomarker of stress as a pain indicator during/after an invasive procedure. While some reported an increase of cortisol (Franck et al., 2011; Grunau et al., 2010), others found no differences (Cignacco et al., 2009; Gibbins et al., 2008a). These conflicting results may be associated with the heterogeneity of study designs, sample size, intensity of the painful procedure, severity of illness, and method of cortisol collection.

Heart rate variability (HRV) is another biomarker that has been substantially studied, especially in the extremely low birth weight infant population. For example, Grunau and colleagues (2001) demonstrated a heightened cardiac sympathetic activity during heel lance where the most significant factors associated with altered behavioural and autonomic pain reactivity at 32 weeks PCA (greater number of previous invasive procedures since birth and GA at birth) were related to a dampened response. After controlling for these variables, exogenous steroid exposure independently contributed to the behavioural and autonomic pain scores, also dampening the response. A summary of recent studies on biomarkers in infant pain is included in Table 35.2.

#### Cortical indicators

There is growing interest on the role of the brain in pain mechanism and transmission of noxious stimuli from the periphery to the central nervous system. The majority of research has been conducted with animals. However, newer non-invasive neuroimaging techniques including electrophysical methods (electroencephalogram—EEG), radiological methods (positron emission tomography—PET), magnetic resonance techniques (magnetic resonance

**Table 35.1** Unidimensional and multidimensional composite measures for acute pain and persistent/ prolonged/ chronic pain

Pain scale	Dimension/ domain	Type of pain	Age level	Indicators	Psychometric properties
<b>Unidimensional single-domain measures</b>					
ABC Scale (Bellieni et al., 2005, 2007)	Behavioural	Acute (procedural)	Preterm/full-term infants	Cry: (a) Pitch of first cry (b) Rhythmicity of bout of crying (c) Cry constancy	<i>Term infants:</i> Interrater reliability: (Cohen's K = 0.83) Intrarater reliability: (Cohen's K = 0.85) Specificity: analgesic/non-analgesic (P < 0.0001); pain/sham (P < 0.0001) Sensitivity: high correlation between ABC and DAN Concurrent validity: (Spearman r = 0.91) Internal consistency: (Cronbach's alpha = 0.76) Practicality: nurses scored as 'good' <i>Preterm infants:</i> Interrater reliability (K = 0.70) Concurrent validity: (r = 0.68; r <sup>2</sup> = 0.45; p < 0.0001) between ABC and PIPP

With HR mean (P < 0.001), BP mean (P < 0.001), HRV (P < 0.001), and BPV (P = 0.007) (Peters et al., 2003)
<b>Unidimensional multiple-domains measures</b>					
Behavioral Indicators of Infant Pain (BIIP) Scale (Holsti and Grunau, 2007a)	Behavioural	Acute (procedural)	23–32 weeks GA	State Facial actions Hand actions	Internal consistency: (r = 0.82) Interrater reliability: (r = 0.80–0.92) Construct validity: (F[1, 86] = 85.9, p < 0.0001) Concurrent validity with NIPS: (earlier born < 29 weeks (EB) r = 0.64, p < 0.0001; later born 29–32 weeks (LB) r = 0.60, p < 0.001). Correlations between the BIIP and mean heart rate (EB r = 0.33, p < 0.05; LB r = 0.50, p < 0.001)
Bernese Pain Scale for Neonates (BPSN) (Cignacco et al., 2004)	Behavioural	Acute (procedural)	27–41 weeks GA with/without ventilation	Alertness Duration of crying Time to calm Skin colour, Eyebrow bulge with eye squeeze, Posture Breathing pattern Interrater reliability: (r = 0.86–0.97)	Intrarater reliability: (r = 0.98–0.99) Construct validity: (P < 0.0001) Concurrent and convergent validity: BPSN compared to VAS and PIPP (r = 0.86, and r = 0.91, P < 0.0001, respectively)
Children's and Infants' Postoperative Pain Scale (CHIPPS) (Büttner and Finke, 2000)	Behavioural	Prolonged (postoperative)	Birth–4 years	Crying Facial expression Posture of trunk and legs Motor restlessness	Internal consistency: (> 1 year) (Cronbach's alpha = 0.96) Interrater reliability: (> 3 years) (r = 0.64–0.77) Content validity Construct and concurrent validity in older subsample (P < 0.001)

(Continued)

Table 35.1 (Continued)

Pain scale	Dimension/ domain	Type of pain	Age level	Indicators	Psychometric properties
Douleur Aigue du Nouveau-ne (DAN) (Carbajal et al., 1997, 2005)	Behavioural	Acute (procedural)	24–41 weeks GA	Facial expression Limb movement Vocalizations/ attempt at vocalizations	Internal consistency: (Cronbach's $\alpha = 0.88$ ) Interrater reliability: ( $r = 0.91$ ) Content validity
Face, Legs, Activity, Cry, Consolability (FLACC) scale (Manworren and Hynan, 2003; Merkel et al., 1997)	Behavioural	Acute (procedural)	Birth to adolescents (also for children with disabilities)	Face Legs Activity Cry Consolability	Interrater reliability ( $K = 0.61$ ) Content validity Concurrent validity ( $P < 0.001$ )
Modified Behavioural Pain Scale (MBPS) (Taddio et al., 1995)	Behavioural	Acute (procedural)	2–6 months	Facial expression Cry Body movement	Interrater reliability: (ICC = 0.95) Internal consistency: ( $r = 0.55$ – $0.66$ ) Test-retest reliability: ( $r = 0.95$ ) Content validity Construct validity: ( $P < 0.01$ ) Concurrent validity: ( $r = 0.68$ – $0.74$ )
<b>Multidimensional composite measures</b>					
Cardiac Analgesic Assessment Scale (CAAS) (Suominen et al., 2004)	Behavioural, Physiological	Prolonged (postoperative)	Birth–mean age = 2.5 years	Papillary size Heart rate Blood pressure Respiratory and motor response	Interrater reliability: ( $r = 0.86$ – $1.0$ ) Content validity Convergent validity: ( $K = 0.33$ ; $P < 0.05$ pre-post bolus)
Crying Requires oxygen Increased vital signs Expression Sleep (CRIES) Scale (Krechel and Bildner, 1995)	Behavioural, physiological	Prolonged (postoperative)	28 weeks GA–6 years	Crying Requires O <sub>2</sub>	Convergent validity (with PIPP and VAS) Concurrent validity: with NIPS and CHIPPS (range $r = 0.30$ – $0.38$ )
Increased vital signs Expression Sleep (CRIES) Scale (Krechel and Bildner, 1995)				Increased vital signs Expression Sleepless	Construct validity and predictive validity: (sensitivity and specificity $> 90\%$ ) Interrater reliability: ( $r = 0.98$ ) Feasibility: global rating for routine use was low (20%) Rated as moderately feasible for clinical practice
COMFORT scale (Ambuel et al., 1992)	Behavioural, physiological	Acute, acute (prolonged), chronic and level of sedation	0–17 years	Alertness, calmness respiratory response Crying Physical movement Muscle tone Facial tension Blood pressure (MAP) baseline Heart rate baseline VAS	Interrater reliability: (Kappa = 0.54–0.93) Internal consistency: (Cronbach's $\alpha = 0.92$ , ICC = 0.82–0.85, $r = 0.90$ – $0.92$ ) Concurrent validity ( $r = 0.75$ , $P < 0.01$ ) Content validity Convergent validity: with clinician judgement ( $r = 0.89$ – $0.96$ ) Concurrent validity: with VAS ( $r = 0.44$ – $0.96$ )
Echelle Douleur Inconfort Nouveau-né (EDIN) (Debillon et al., 2001)	Behavioural, physiological	Prolonged (postoperative)	26–36 weeks GA	Facial expression Movement Sleep Consolability	Interrater reliability: ( $k = 0.69$ , $r = 0.59$ – $0.74$ ) Internal consistency: (Cronbach's $\alpha = 0.92$ ) Content validity Construct validity: ( $P < 0.000$ )

(Continued)

**Table 35.1** (Continued)

Pain scale	Dimension/ domain	Type of pain	Age level	Indicators	Psychometric properties
EVENDOL (Moreaux, 2010)	Behavioural, physiological	Acute (pain in emergency)	1 month– 6 years	Complaint Grimace Movements Postures Interaction with surroundings	Interrater reliability: ( $r > 0.9$ , weighted kappa 0.7 to 0.9) Construct validity: before /after nalbuphine ( $p < 0.0001$ ), at mobilization ( $p = 0.0011$ ) Concurrent validity: between VAS and EVENDOL $> 0.8$ ( $p < 0.0001$ ); between EVENDOL and other scales (EDIN, CHEOPS, FLACC, TPPPS): 0.5 to 0.93 Content validity: (Cronbach coefficient = 0.83 to 0.92).
Faceless acute neonatal pain scale (FANS) (Milesi et al., 2010)	Behavioural, physiological	Acute (procedural)	Preterm infants	Heart rate variation Acute discomfort Limb movements Vocal expressions	Inter-rater agreement: ( $r = 0.92$ ) Internal consistency: (Cronbach's $\alpha = 0.72$ ) Concurrent validity: FANS and DAN (ICC = 0.88)
Hartwig Score (Hünseler et al., 1991)	Behavioural, physiological	Acute	Infants	Motor response Grimacing Eyes Respiration Aspiration	Interrater reliability: (ICC = 0.934) Internal consistency: all items (Cronbach's alpha = 0.867) Concurrent validity: between Hartwig Score and VAS: mean of the differences of 0.77 (0.77); 95% CI of 0.508–1.03 (0.411; 1.129) and levels of agreement from –1.76 to 3.23 (–1.74 to 3.0); between Hartwig Score and Comfort scale: mean differences of 0.15 (0.34); 95% CI of 0.013–0.287 (0.104; 0.576) and levels of agreement from –1.49 to 1.77 (–1.13 to 1.82) (Hünseler et al., 2011)
Liverpool Infant Distress Scale (LIDS) (Horgan and Choonara, 1996; Horgan et al., 2002)	Behavioural, physiological	Prolonged (postoperative)	Neonates	Facial expression Sleep pattern Cry quantity and quality, Spontaneous movement and excitability Flexion of fingers, toes, Tone	Internal consistency: ( $r = 0.84$ – $0.94$ ) Interrater reliability: ( $r = 0.74$ – $0.88$ ) Intrater reliability: ( $r = 0.1$ – $0.96$ ) Content validity Discriminant validity: ( $P = 0.004$ – $0.0000$ )
Multidimensional Assessment of Pain Scale (MAPS) (Ramelet et al., 2007a, 2007b)	Behavioural, physiological	Prolonged (postoperative)	0–31 months	Vital signs Breathing pattern Facial expressions Body movement State of arousal	Internal consistency: (Cronbach's alpha = 0.62 at baseline, 0.80 at 15 min, 0.37 at 30 min, 0.26 at 60 min. When 'vital signs' was deleted, internal consistency at baseline, 15, 30, and 60 min improved $r = 0.64, 0.79,$ 0.67, and 0.71) Concurrent validity: between MAPS and FLACC: mean of differences 0.44 (CI: 0.18–0.71); limits of agreement = –1.22 to 2.09; between MAPS and VAS: mean of differences 0.25 (CI of 0.02–0.49); limits of agreement –1.24 to 1.74 Clinical utility: reported as useful in preverbal children (median 2, IQR 1) and moderately simple (median 2, IQR 0). Median observation time was 2 min (IQR 4) and mean assessment time was 35.3 ( $\pm 26$ ) sec
Modified Infant Pain Scale (MIPS) (Buchholz et al., 1998)	Behavioural, physiological	Prolonged (postoperative)	4–30 weeks PNA	Sleep Facial expression Quality of cry Spontaneous motor activity, Excitability/ responsiveness to stimulation, Flexion fingers/toes,	Interrater reliability: ( $r = 0.85$ ) Content validity Convergent validity: in dichotomous rating ( $P < 0.0001$ )

Table 35.1 (Continued)

Pain scale	Dimension/ domain	Type of pain	Age level	Indicators	Psychometric properties
				Sucking Overall tone, Consolability, Sociability, Change in HR, BP Fall in O <sub>2</sub> saturation	
Modified Postoperative Comfort Score (Guinsburg et al., 1998)	Behavioural, physiological	Prolonged (mechanical ventilation)	< 32 weeks GA	Sleep Facial expression Sucking Hyper-reactivity Agitation Hypertonicity Toes/fingers flexion Consolability	Convergent validity: in bedside ( $P < 0.00001$ ) and laboratory video coding ( $P = 0.02$ ) Content validity Divergent validity: placebo and analgesic samples ( $P < 0.05$ )
Modified Postoperative Comfort Score (Guinsburg et al., 1998)	Behavioural, physiological	Prolonged (postoperative)	Preterm infants	Sleep Facial expression Activity Tone Consolability Cry Sociability	Content validity Discriminant validity: ( $P < 0.0001$ )
Napean Neonatal Intensive Care Unit Pain Assessment Tool (NNICUPAT) (Marceau, 2003)	Behavioural, physiological, and contextual	Acute (procedural)	Ventilated infants 25–36 weeks GA	Facial expression Body movement Colour Saturation Respiration Heart rate Nurse perception of pain	Content validity Interrater reliability: before and during procedure ( $r = 0.88$ ) Interrater reliability: after procedure ( $r = 0.48$ ) Concurrent validity: during procedure ( $r = 0.01$ )
Neonatal Infant Pain Scale (NIPS) (Lawrence et al., 1993)	Behavioural, physiological	Acute (procedural)	Preterm and full-term	Facial expression Cry Breathing patterns Arm movement Leg movement State of arousal	Interrater reliability: ( $r = 0.92–0.97$ ) Internal consistency: ( $0.87–0.95$ ) Content validity Concurrent validity: ( $r = 0.53–0.83$ )
Neonatal Pain, Agitation and Sedation Scale (N-PASS) (Hummel et al., 2003, 2008, 2010)	Behavioural, physiological	Acute (procedural) and prolonged (mechanical ventilation)	23–40 weeks GA	Crying/irritability Behavioural state Facial expression Extremities/tone Vital signs (HR, RR, BP, O <sub>2</sub> saturation)	Interrater reliability: ( $r = 0.85–0.95$ ) Intrarater reliability: (Spearman's rho $r = 0.874$ , $P < 0.0001$ ). Construct (discriminate) validity: ( $Z = -6.429$ , $P < 0.0001$ ) Internal consistency: (Cronbach's alpha = $0.84–0.89$ ) Convergent validity: with PIPP ( $r = 0.83$ with high pain scores, $r = 0.61$ with low pain scores)
Riley Infant Pain Scale (RIPS) (Schade et al., 1996)	Behavioural, physiological	Prolonged (postoperative)	<3 years or children unable to verbalize pain	Facial expression Body movement Sleep Verbal/vocal Consolability Response to movement/touch	Interrater reliability: (ICC = $0.53–0.83$ ; lower <1 month age group) Internal consistency: ( $r = 0.73–0.88$ ) Content validity Discriminant validity: ( $P < 0.001$ )

(Continued)

**Table 35.1** (Continued)

Pain scale	Dimension/ domain	Type of pain	Age level	Indicators	Psychometric properties
Pain Assessment in Neonates Scale (PAIN) (Hudson-Barr et al., 2002)	Behavioural, physiological	Acute (procedural)	26–47 weeks GA	Facial expression Cry Breathing patterns Extremity movement State arousal O <sub>2</sub> saturation Increased heart rate	Content validity Concurrent validity: ( $r = 0.93$ )
Pain Assessment Tool (PAT) (Hodgkinson et al., 1994)	Behavioural, physiological and contextual	Prolonged (postoperative)	27 weeks to full-term	Posture/tone Sleep pattern Expression Colour Cry Respirations Heart rate O <sub>2</sub> saturations Blood pressure Nurse perception	Interrater reliability: ( $r = 0.85$ ) Content validity Convergent validity: ( $r = 0.38$ ) Concurrent validity: ( $r = 0.76$ ) (Spence et al., 2005)
Postoperative Pain Score (POPS) for Infants (Barrier et al., 1989)	Behavioural, physiological	Prolonged (postoperative)	1–7 months	Infant sleep during the preceding hour Facial expression Cry	Interrater reliability: ( $r = 0.79$ – $0.88$ ) Content validity Discriminant validity: ( $P < 0.0001$ )
				Motor activity Excitability Flexion Sucking Tone Consolability	
Premature Infant Pain Profile (PIPP) (Stevens et al., 1996)	Behavioural, physiological, and contextual	Acute (procedural)	Term and preterm neonates	GA Behavioural state Heart rate O <sub>2</sub> saturation Brow bulge Eye squeeze Nasolabial furrow	Interrater reliability: ( $r > 0.89$ for total score) Intrarater reliability scores: ( $r = 0.95$ ) Internal consistency: ( $\alpha = 0.59$ – $0.76$ ) Construct validity: ( $P < 0.05$ ) Convergent validity: between PIPP and CRIES: ( $r = 0.447$ ; $P < 0.001$ ; $r = 0.292$ to $0.472$ ; $P < 0.005$ , respectively; ICC = $0.6139$ ; 95% CI: $0.4$ – $0.76$ ); between PIPP and FLACC: ( $r = 0.462$ to $0.521$ ; $P < 0.01$ ); between PIPP and N-PASS: ( $r = 0.81$ to $0.83$ ) during severe pain and ( $r = 0.61$ ) for minimal-to-moderate pain. Feasibility: staff nurses able to use after a brief explanation and practice session. (Jonsdottir and Kristjansdottir, 2005). Clinical utility: Schiller (1999) examined the PIPP and the CRIES. Both measures were rated as clinically useful: PIPP rated higher on acceptability and the CRIES rated higher on completion time and cost.
Premature Infant Pain Profile–Revised (PIPP–R) (Gibbins, 2008b; Stevens et al., 2012)	Behavioural, physiological, and contextual	Acute (procedural)	Term and preterm neonates	Same as PIPP but GA and behavioural state scored only when subtotal score of behavioural and physiological indicators $> 0$	Convergent validity: between PIPP and PIPP–R: ( $R^2 = 0.93$ , $p < 0.0001$ ) for ELBW infants during diaper change ( $R^2 = 0.91$ , $p < 0.0001$ ) and heel lance ( $R^2 = 0.98$ , $p < 0.0001$ ) conditions. PIPP and PIPP–R scores were highly correlated ( $R^2 = 0.98$ , $p < 0.001$ ) for infants 25–41 weeks GA

(Continued)

**Table 35.1** (Continued)

Pain scale	Dimension/ domain	Type of pain	Age level	Indicators	Psychometric properties
					Construct validity: PIPP-R scores were significantly lower during diaper change [mean 8.3(SD = 2.9)] compared to heel lance [mean 9.9 (SD= 3.1); (t (95) = 4.51, p = 0.036)]. Feasibility: Mean scores on each feasibility scale (median of 4/of 5).
Scale for Use in Newborns (SUN) (Blauer and Gerstmann, 1998)	Behavioural, physiological (movement, facial expression biomarkers, biomarkers)	Prolonged (excluded postoperative)	24–40 weeks GA	Central nervous system state Breathing Movement Tone, face Heart rate Mean blood pressure	Content validity Discriminant validity: (p < 0.05–0.01)

**Table 35.2** Biomarker indicators of neonatal/ infant pain

Indicator(s)	Reference	Study design/methods	Main results
<b>Cortisol</b>			
Behavioural Biochemical	Cignacco et al., 2009	Single group, exploratory repeated measures design exploring the variability in pain response in preterm infants who received sucrose during routine heel stick (n = 9)	72–94% within-subject variability No significant differences in cortisol before and after the heel sticks (p = 0.55). A general gradual decrease of cortisol levels across time
Behavioural Physiological Biochemical	Franck et al., 2011	Prospective observational study comparing indices of pain in critically ill full-term neonates following cardiac surgery (n = 81)	A 27% difference in COMFORT scores between tissue damaging and non-tissue damaging procedures (P < 0.001). COMFORT score and the high-frequency HRV showed inverse correlations with opioid dose and plasma levels over the first 48 h postoperatively; after accounting for clinical variables, only COMFORT score remained significant (P < 0.001). Both behavioural and physiological variables accounted for 45% and 15% respectively of the variance in COMFORT scores (P < 0.001). Plasma cortisol increased postoperatively but no change in urinary cortisol
Physiological Behavioural Biochemical	Gibbins et al., 2008a	Prospective crossover design comparing physiological, behavioural and biochemical responses to painful and non-painful procedures in ELGA infants (n = 50)	Facial actions—brow bulge (t = −4.6, p < 0.001), eye squeeze (t = −3.5, p < 0.002), nasolabial furrow (t = −3.3, p < 0.002) and vertical mouth stretch (t = −2.6, P < 0.01), increased post heel lance. No changes in physiology, body movement, or cortisol following the heel lance
Behavioural Physiological Biochemical	Grunau et al., 2010	Prospective cohort study examining cortisol reactivity during immunization in preterm (n = 99) and full-term (n = 39) infants at corrected age 4 months	Cortisol (P = 0.011), facial activity (P < 0.0001), and HR increased (P < 0.0001) during immunizations. Cortisol was lower in preterm ELGA and VLGA boys, compared with full-term boys (P = 0.006)
Behavioural Biochemical	Holsti et al., 2007b	Randomized cross-over design examining facial responses, adrenocorticotrophic hormone (ACTH) and cortisol levels in preterm infants during routine nursing procedures (n = 90 preterm infants: extremely low gestational age (ELGA: 28 weeks); very low gestational age (VLGA: 29–31 weeks))	Facial actions increased significantly from baseline during clustered care (p = 0.001), and continued during the recovery phase. The correlation between ACTH and cortisol differed significantly between the two GA groups. During clustered care, ELGA infants showed no relationship between ACTH and cortisol, whereas VLGA infants showed a significant correlation (r = 0.62, p = 0.0001)
Biochemical	Schaffer et al., 2009	Prospective cohort study comparing salivary cortisol and cortisone levels during rest and a pain-induced stress event in small for gestational age (SGA) and appropriate for gestational age (AGA) neonates 34 weeks of gestation (n = 58)	In AGA neonates, salivary cortisol and cortisone levels significantly increased after the stress event (P < 0.05) while SGA infants exhibited a blunted response

(Continued)

Table 35.2 (Continued)

Indicator(s)	Reference	Study design/methods	Main results
Biochemical	Yamada et al., 2007	Prospective cohort study to determine differences between (a) hair cortisol levels in term and preterm infants exposed to stress in the NICU and (b) hair cortisol levels and severity of illness (n = 60 infants >25 weeks GA)	No significant differences between the hair cortisol levels in hospitalized term and preterm infants. Hospitalized infants had significantly higher hair cortisol levels than healthy term infants (t (76) = 2.755, p = 0.004)  Term NICU infants showed a statistically significant association between total number of ventilator days and hair cortisol levels: for every extra day on the ventilator, hair cortisol levels increased on average by 0.2 mol/g (p = 0.03)
<b>Heart rate variability (HRV)</b>			
Behavioural Physiological	Faye et al., 2010	Prospective cohort study exploring HRV to pain in the full-term newborn (n = 28). Postoperative pain assessed using EDIN scale at the end of the 2 h recording period	Mean EDIN scores were 21 and 72 in respectively the groups 'Low EDIN' and 'High EDIN.' HFVI was significantly lower in the 'High EDIN' group than in the 'Low EDIN' (0.70.2 vs. 1.20.3, respectively; P < 0.01). An HFVI < 0.9 predicted an EDIN score 5, with a sensitivity of 90%, and a specificity of 75%
Physiological	Padhye et al., 2009	Prospective repeated measures cohort study to characterize the HRV response of high-risk very low birth weight infants (<1500 g) from 23–38 weeks GA (n = 38 infants) to heel lance procedure and venepuncture	HRV in both bands decreased during pain (P < 0.001), followed by a recovery to near-baseline levels (P = 0.166). Venepuncture and mechanical ventilation attenuated the HRV response to pain (P = 0.024 and P = 0.001 respectively). HRV at the baseline increased with GA but the growth rate of high-frequency power was reduced in mechanically ventilated infants
Physiological Behavioural	Stevens et al., 2007	Prospective observational cohort study comparing pain responses to heel lance from infants at high (Cohort A, n = 54), moderate (Cohort B, n = 45) and low (Cohort C, n = 50) risk for NI (n = 149)	A significant cohort by phase interaction for total facial action (F(6, 409) = 3.50, p = 0.0022) and 4 individual facial actions existed; with Cohort C demonstrating the most facial action. A significant Phase effect existed for increased maximum HR (F(3, 431) = 58.1, p = 0.001), minimum HR (F(3, 431) = 78.7, p = 0.001), maximum O <sub>2</sub> saturation (F(3, 425) = 47.6, p = 0.001), and minimum O <sub>2</sub> saturation (F(3, 425) = 12.2, p = 0.001) with no cohort differences  Cohort B had significantly higher minimum (F(2, 79) = 3.71, p = 0.029), and mean (F(2, 79) = 4.04, p = 0.021) fundamental cry frequencies  A significant phase effect for low/high-frequency HRV ratio (F(2, 216) = 4.97, p = 0.008) was found with the greatest decrease in Cohort A. Significant cohort by phase interactions existed for low- and high-frequency HRV

imaging—MRI), and near-infrared spectroscopy (NIRS), have been explored to try and better understand structural, biochemical, or functional neuronal activity in the brain's response to noxious stimulation. A summary of the most recent studies are included in Table 35.3.

Recently, Brummelte et al. (2012), using MRI, three-dimensional magnetic resonance spectroscopic imaging, and diffusion tensor imaging demonstrated that greater numbers of skin-breaking procedural pain indicators may contribute to impaired brain development in preterm infants. Fabrizi and colleagues (2011) systematically mapped the maturation of tactile and nociceptive activity in the developing human brain using EEG signals. Specific neural circuits for discrimination between touch and nociception emerged from 35 to 37 weeks GA in the human brain.

Although, biomarkers, cortical indicators and cognitive mapping provide novel and objective means to exploring the infant's response to pain, decoding their complex and variable patterns and comparing them to behavioural pain indicators and composite measures has not been sufficiently explored. Carefully designed measurement studies comparing cognitive indicators with established

measures in appropriate designs are needed. For example, for randomized controlled trials, a measure of methodological quality such as the CONSolidated Standards of Reporting Trials (CONSORT, 2010) statement that includes whether a validated measure, appropriate randomization, and follow-up of outcomes are used should be incorporated as a guideline for reporting the methodological quality of published studies and responsible external generalization of the results.

## Current clinical practice guidelines, policies, and procedures

An important aspect of improving clinical outcomes is to ensure that the most recent evidence is effectively translated into clinical practice. This translation needs to be supported by inclusion of recommendations for pain assessment within wider pain management guidelines. To date, several published guidelines from professional organizations have included recommendations on pain assessment and management (see Table 35.4). The majority do not focus on children, although there are a few that are specific to children

**Table 35.3** Cognitive indicators of neonatal/infant pain

Indicator	Reference	Study design/methods	Main results
Magnetic resonance imaging (MRI)	Brummelte et al., 2012	Prospective cohort study (n = 86 preterm infants 24–32 weeks GA) to examine relationship between procedural pain and early brain development	Greater numbers of painful procedures were associated with reduced white matter (p = 0.028) and reduced subcortical grey matter (p = 0.004) after adjusting for multiple clinical factors
Electro-encephalography (EEG)	Fabrizi et al., 2011	Prospective cohort study (N = 18 infants 37–45 weeks GA; and N = 41 infants 28–45 weeks GA (born at 24–41 weeks GA)) comparing touch or heel lance	Occurrence in the preterm infants was significantly less than in the full-term infants (p = 0.01 tactile potential; p = 0.01 nociceptive-specific potential). Latencies of tactile and nociceptive-specific potentials were shorter in full-term infants than in premature infants. Neuronal bursts were significantly greater in preterm infants than term infants whether evoked by touch (p = 0.048) or noxious lance (p < 0.001) Neural circuits for discrimination between touch and nociception emerge from 35–37 weeks GA in the human brain
	Slater et al., 2010	Pilot prospective cohort study to determine whether cortical neurons are specifically activated by noxious stimuli in newborns (N = 10 infants 35–39 weeks PMA) using EEG recording following a routine heel lance	The potential was observed in the central electrodes and characterized by a positivity that occurs at approximately 560 msec post-stimulus The magnitude of the nociceptive-specific potential was not dependent on sleep state, whereas an earlier potential, which was sleep-state dependent, was evoked by both noxious and non-noxious stimulation Researchers report that results provide the first direct evidence of specific noxious-evoked neural activity in the infant brain
Electro-myography (EMG)	Schasfoort et al., 2008	Prospective cohort study to determine the feasibility of long-term, objective, and continuous measurement of peripheral motor parameters to discriminate between pain and no pain in hospitalized pre-verbal infants during (a) acute painful procedure: n = 9 (5–175 days of age); and (b) postoperative pain: n = 14 infants (age range 45–400 days for age) measured for prolonged periods (mean 7 h) using acceleration sensors on one arm and both legs, and two muscle activity parameters derived from EMG sensors	<i>Acute painful procedure:</i> the accelerometry-based parameters legs activity and overall extremity activity (i.e. mean of arm and legs) was significantly higher during heel lance than before or after lance (p ≤ 0.001) <i>Post-operative pain:</i> relationships existed between accelerometry-based overall extremity activity and COMFORT scale (r = 0.76, p < 0.001), and between EMG-based wrist flexor activity and COMFORT (r = 0.55, p < 0.001, for a subgroup of 7 infants) Researchers conclude that long-term, objective, and continuous measurement of peripheral motor parameters is feasible, has high potential, and is promising to assess pain in preverbal hospitalized infants
Near-infrared spectroscopy (NIRS)	Bartocci et al., 2006	Prospective cohort study to study patterns of supraspinal pain processing in neonates (N = 40 preterm neonates at 28–36 weeks GA) and at 25–42 h following standardized tactile (skin disinfection) and painful (venepuncture) stimuli. Changes were monitored by NIRS over both somatosensory cortices in 29 newborns, and over the contralateral somatosensory and occipital areas in 11 newborns. HR and peripheral O <sub>2</sub> saturation (SaO <sub>2</sub> ) were recorded simultaneously with NIRS parameters: oxygenated (HbO <sub>2</sub> ), deoxygenated, and total haemoglobin were also measured	Tactile stimulation produced no changes in HR or SaO <sub>2</sub> HR increased in the first 20 sec (p < 0.001), while SaO <sub>2</sub> decreased during the 40 sec after venepuncture (p < 0.0001). Following tactile or painful stimulation, [HbO <sub>2</sub> ] increased bilaterally (p < 0.0001) Pain-induced [HbO <sub>2</sub> ] increases in the contralateral somatosensory cortex (p < 0.05) were not mirrored in the occipital cortex (p > 0.1) Pain-related [HbO <sub>2</sub> ] increases were significantly more pronounced in male neonates, inversely correlated with GA and directly correlated with PNA. Researchers concluded that painful and tactile stimuli elicit specific haemodynamic responses in the somatosensory cortex, implying conscious sensory perception in preterm neonates
	Slater et al., 2006	Prospective cohort study to determine whether premature infants process pain at a cortical level (N = 18 infants 25 and 45 weeks PMA) assessed by changes in cerebral oxygenation over the somatosensory cortex in response to noxious stimulation using real-time NIRS	Noxious stimulation produced a clear cortical response, measured as an increase in total haemoglobin concentration [HbT] in the contralateral somatosensory cortex, from 25 weeks. Cortical responses were significantly greater in awake versus sleeping infants. In awake infants, the response in the contralateral somatosensory cortex increased with age while latency decreased with age. Researchers concluded that noxious information is transmitted to the preterm infant cortex from 25 weeks, highlighting the potential for both higher-level pain processing and pain-induced plasticity in the human brain

Guideline source/association	Content	Pain assessment measures recommended	Feasibility/clinical utility
Nursing Best Practice Guideline—Assessment & Management of Pain Canada (Registered Nurses Association of Ontario 2002; revised 2007)	Guideline development Process and responsibilities Interpretation of evidence Definition of terms Practice, education, organization and policy Recommendations Evaluation and monitoring	PIPP NIPS	174 pages Guideline for all populations across the lifespan Recommended timing: (a) at least once a day, (b) on a regular basis according to the type and intensity of pain and the treatment plan. Recommended documentation: (a) on a standardized form specific to the population and setting; (b) include initial, comprehensive and re-assessment; (c) document regularly and routinely on forms that are accessible to all clinicians; (d) teach individuals and families (as proxy recorders) to document pain assessment on the appropriate tools
Pain Assessment in the Nonverbal Patient: Position Statement with Clinical Practice Recommendations United States (American Society for Pain Management Nursing, 2006)	Discusses pain assessment in all non-verbal patients Background information on pain assessment in neonates	CHEOPS CHIPPS COMFORT CRIES DSVNI PIPP RIPS UWCH	9 pages Recommended timing and documentation; (a) Pain should be routinely monitored, assessed, reassessed, and documented clearly to facilitate treatment and communication; (b) after intervention and regularly over time, and (c) documented in a readily visible and consistent manner that is accessible to all health care providers
Prevention and Management of Pain in the Neonate: An Update (American Academy of Pediatrics, Committee on Fetus and Newborn and Section on Surgery, Section on Anesthesiology and Pain Medicine, Canadian Paediatric Society and Fetus and Newborn Committee, 2006)	Pain and stress in the neonate Pain assessment Recommendations	CRIES COMFORT PIPP NIPS N-PASS NFCS PAT SUN EDIN BPSN	Specific to neonates Focused and easy to read Age appropriateness of measures indicated Recommended timing: neonates should be assessed for pain routinely and before and after procedures No specific recommendations for documentation of pain assessment

and even fewer for neonates and infants. The major content areas covered in these guidelines include background material on pain and its consequences, summaries of current evidence in prevention and management of pain with specific procedures (e.g. heel lance) and recommendations for implementation. From a systematic review of pain assessment guidelines using Medical Subject Headings (MeSH) terms *Pain Measurement*, *Pain Management*, *exp Pain/cl, di [Classification, Diagnosis]*, *Guideline or practice guideline*, *Intensive Care Units*, *Neonatal* and limited to newborn, English language from 1946 to present, only seven guidelines included specific recommendations of neonatal or infant pain assessment measures; the PIPP and NFCS were most commonly recommended. Six guidelines recommended specified timing and frequency of pain assessment. The recommendations were generally consistent across timing of assessments and documentation every 4 to 6 h or as indicated by the pain scores or clinical condition of the neonate. Overall, although great efforts have been made by researchers to consolidate evidence into practice guidelines, several gaps remain. Also, although some guidelines are clear with user-friendly tables and flow diagrams, many require more concrete recommendations.

For example, more specific directives (e.g. care paths or care plans) that include clear, succinct statements on pain assessment with visual decision-making aids and specific recommendation for timing, documentation of assessment measures utilized and scores, and action plans to follow with assessment results targeted specifically for the neonatal and infant populations are needed.

## Challenges and controversies associated with neonatal and infant pain assessment

There has been a long history of neglect of pain during infancy. Although many improvements have been achieved in the wake of ever-increasing knowledge expansion in the past few decades, future advancement will depend on adequately addressing and resolving current theoretical, clinical, research, and KT challenges and controversies.

### Theoretical challenges and controversies

Science, as a social institution, has not stimulated adequate support for a comprehensive understanding of the interpersonal and

social aspects of pain within the infant. The current focus has been more on the biology of pain with diminished importance placed on the psychological aspects (Craig, 2009). Clearly defining pain in infants in accurate terms that are broadly applicable to the neonatal and infant population is essential. Without this definition, terms such as nociception, pain, stress, distress, as well as analgesia, calming, and comfort are often used interchangeably or incorrectly and may result in inadequate measurement and erroneous conclusions regarding pain management.

The *absence of a behavioural pain response* to stimulation which would normally be painful (e.g. heel lance) is particularly in need of exploration in relation to pain in infants. Absence of pain response as measured by behavioural or a composite of behavioural and physiological indicators, has been reported to occur in approximately 20% of infants (Johnston et al 1999). This may be because: (1) the response is so weak that it escapes observer detection, (2) the infant may be incapable of mounting any response due to extenuating circumstances (e.g. severity of illness, extreme prematurity), or (3) the infant does not perceive the stimulus as painful. Regardless of the reason, this is a serious situation because pain behaviour in response to tissue damage is such a universal response in other populations and makes evolutionary sense. It is also difficult to dispute the importance of behavioural indicators in particular given their consistency across populations, situations, and contexts. Furthermore, it places infants in a vulnerable situation where they are completely dependent on the judgement of caregivers to make accurate conclusions surrounding their care and pain management.

Similarly, *absence of a physiological (e.g. heart rate (HR)) or cortical response (e.g. EEG)* to nociceptive stimulation also does not necessarily indicate absence of pain (or analgesia, if an intervention is being evaluated). It may indicate that an inappropriate response was measured or that the sensitivity of the measure or the analyses was questionable. These issues illustrate the need for sensitive and valid indicators of pain and clarity surrounding the terms 'pain', 'nociception', and 'analgesia' in infants amongst clinicians and researchers in relation to pain assessment. Future investigation needs to focus on whether a relationship exists between behavioural observational indicators of pain (e.g. facial action) and biomarkers or cortical indicators associated with noxious stimulation, and under what conditions.

Progress has been primarily made in the conceptualization and assessment of acute pain in neonates and infants. Further consideration of unique developmental and communication processes requires further attention. Key unanswered questions relate to (1) how repeated pain at certain stages of the infant's development influences pain expression and (2) what are the crucial elements from the infant's interaction with the environment and caregivers that influence pain expression and assessment by caregivers?

Progress towards the optimal management of pain during infancy also demands an exploration of pain beyond the acute-procedural (e.g. immunization pain), acute-repetitive (e.g. multiple heel lances), or acute-prolonged (e.g. postoperative pain) domains. Examination of the existence of a pathological pain state, whereby pain continues beyond expectation or persists for a significant portion of the infant's existence is crucial. Knowing that the human nervous system is extremely malleable in response to noxious environmental

influences during infancy suggests that steps taken to manage pain need to be varied and tailored to the individual infant's needs.

## Clinical challenges and controversies

Clinical challenges in pain assessment relate to the integration of knowledge into practice or KT. From the measurement perspective, difficulty in identifying a criterion ('gold standard') for determining the validity of the phenomenon, lacking the subjective, unique and private nature of the symptom is paramount (Sidani, 2003). Behavioural and physiological variables often correlate inconsistently and poorly with each other and with other indicators (e.g. correlation is often around 0.3). This incongruence and the lack of the patient's self-report, often brings into question the validity of the measure or indicator, creates controversies on the benefits and disadvantages of unidimensional versus multidimensional measurement approaches, and may affect judgement about pain intensity and decision-making about the effectiveness of interventions. The multidimensionality of the pain phenomenon in measurement is often vigorously debated; whereas some lobby for the simplicity of a single indicator of pain, many feel a multidimensional approach is essential for a comprehensive understanding of the experience that informs individualized and effective interventions. Supporters of a more unidimensional approach, fail to articulate how scores on individual indicators or groups of indicators can be viewed to comprehensively provide accurate information to the clinician making decisions at the bedside. Pain intensity is most often the only dimension reported, when occurrence, frequency, duration, impact, meaning, and response are other important information required.

With the development of a broad array of measures for assessing acute pain, selection of the 'best' pain measure becomes a challenge. Developing clearly articulated selection criteria for choosing a measure for clinical and/or research purposes is essential. These criteria could include: (1) validity (measuring accurately the phenomenon of interest; being responsive to changes in the phenomenon), (2) reliability (measuring with the least amount of measurement error so that the score is reliable and reproducible across raters and time), (3) feasibility (ease of scoring, time, cost, clarity of instructions), and (4) clinical utility (ability to use pain scores for a particular infant, in a particular setting, in a meaningful way to make decisions on future pain management strategies).

Despite the plethora of existing pain measures, there is still a paucity of validated measures for the most vulnerable groups of infants who are most critically ill, paralysed, and preterm, at the end of life or with severe neurological impairments. For example, few measures have been validated with the most preterm or extremely low gestational age (ELGA) infants. Because of their immature pain processing, stress-response systems, and development, these infants' responses may be different or at least more subtle and difficult to detect than those of more mature neonates. In addition, non-painful touch and pain responses are often similar. This phenomenon is thought to be due to the wide receptive fields that do not allow for differentiation between these two types of stimuli, thus making it difficult for the care provider to discern whether the infant is experiencing pain or not or whether a targeted intervention is effective. Yet these infants have large numbers of painful events for diagnosis and treatment. Thus, there is an urgent need to develop new measures or validate existing measures for this population.

Routine pain assessment using validated measures is generally purported to be the basis of timely and effective pain management and quality care. These pain practices represent a key component in pain guidelines, policies, and professional standards; yet, pain assessment in infants is not universal or even well integrated into clinical care. Franck and Bruce (2009) suggest that there is insufficient evidence to evaluate the effectiveness of standardized pain assessment in terms of process or clinical outcomes. More research on the efficacy, effectiveness, and cost benefit of standardized pain assessment in relation to clinical and process outcomes needs to be considered as existing research on the use of standardized pain assessment tools has limited evidence for improved process or patient outcomes. Furthermore, a misalignment may exist between the necessity of engaging care providers in accurate assessment of pain in the non-verbal individual and their ability and motivation to do so: 'Poor compliance with pain assessment guidelines may not simply be an issue of the "research-to-practice gap", but it may indicate unspoken resistance to use of methods that are overly simplistic, burdensome to patients, often inaccurate and perhaps even disrespectful of clinical expertise and experience' (Franck and Bruce, 2009, p. 19).

### Research and KT challenges and controversies

Several areas for future research have been indicated to improve and expand pain assessment in neonates and infants. Unanswered questions continue to be posed on the most optimal measurement approach as well as the feasibility and clinical utility of existing measures and indicators. Without seeing clinical benefit of pain assessment for the infants, there is little hope for engaging clinicians in this most important aspect of quality patient care. There is clear debate on the value and limitations of unidimensional and multidimensional approaches to measurement and potential ways to resolve these issues. Pain is well entrenched within the biomedical model of providing health care and future research needs to explore the influence of the context of pain assessment in relation to individual (e.g. their capacity and sensitivity to detect pain in others) and system (e.g. culture of unit, priority of pain management, leadership, timeliness, busyness, expectations) factors that may influence assessing and management of pain. Strategies to facilitate the translation of what we 'know' into what we 'do' for infants and their families in relation to assessment and management of pain is also lacking. KT strategies that include reminders, education and educational outreach, and audit and feedback need to be better incorporated into changing behaviours or health care professionals to enable pain practice changes and ultimately clinical outcomes.

### Summary

Pain assessment in neonates and infants is complex and challenging. Although a broad variety of pain measures have been developed and validated, many fall short of meeting the needs of this population; especially those who are most vulnerable, preterm, ill, or cognitively or developmentally challenged. Lack of a gold standard continues to plague pain assessment in infants; yet clinically there is a need to use the best measures available to attempt optimal pain management. Biomarkers and cortical indicators are currently being investigated to expand our understanding of pain and its effects in infants. The need to move beyond acute procedural

pain and concentrate on accurately assessing pain that is prolonged, persistent, or palliative is crucial. Integrating the science of measurement with clinical excellence remains a challenge for clinicians and researchers alike.

#### Case example

Baby C was born at 27 weeks, is now 15 days old and presented with necrotizing enterocolitis (NEC) and bowel perforation. Her condition is unstable with poor perfusion. She is intubated, ventilated, and is being stabilized for the operation room (OR). A peripheral arterial line insertion was attempted but unsuccessful. She is lethargic with minimal spontaneous movement. The vital signs are: heart rate (HR) 179, respiratory rate (RR) 60, blood pressure (BP) 50/32 (25), oxygen saturation 92, ventilation rate 40/min, pressures 18/7 O<sub>2</sub> 55%O<sub>2</sub>. The nurse suspects the baby is in pain, because when she checks the abdominal girth she notices that the baby is wincing. She does not have time to complete a formal assessment using a validated pain measure.

The surgery was completed. Upon return from the OR, the baby was not reversed from anaesthetic and displayed minimal movement. The vital signs were HR 180, BP 56/26 (30), O<sub>2</sub> sat 95 in 70% O<sub>2</sub>. The baby's colour is pale. The PIPP score is 9. A morphine infusion of 10 mcg/kg/min is started. The vital signs 1 h later are: HR 165, BP 60/32 (40), O<sub>2</sub> sat 92 in 40% O<sub>2</sub>.

During rounds the next day, pain assessment of the baby was reviewed with the following discussion:

1. A pain assessment score should be completed on admission as per hospital pain guidelines. Clinicians need to think about pain as the fifth vital sign. Although the nurse was extremely busy, it was important to complete a pain score and inform the doctor that she suspected the baby was in pain with a validated pain score.
2. A morphine infusion could have been started prior to the OR to reduce the baby's pain.
3. Postoperative guidelines were reviewed and a plan for frequent monitoring of pain was posted at the bedside as per the guidelines.

## CHAPTER 36

# Self-report: the primary source in assessment after infancy

Carl L. von Baeyer

### Summary

Self-report is the primary source of information for assessment of pain and measurement of its intensity in children age 3 years and older. This chapter provides an overview of the variables addressed in assessment, specific tools used to obtain self-reports, and interpretation of pain scores. Challenges include establishing whether children are able to understand and use self-report scales and interpreting self-reported pain scores when they conflict with clinicians' observation. New developments in self-report assessment are introduced, such as new support for the use of numerical rating scales and development of computer and smartphone self-report tools. Recommendations are provided supporting integration of self-report of pain in pain management.

### Statement of aims

Using information in this chapter, clinicians will be able to choose, administer, understand, and interpret appropriate self-report tools to assess and measure pain in children 3 years of age and older.

### Introduction

#### The nature of self-report

A self-report is an oral, written, or non-verbal account or portrayal of a person's own thoughts, feelings, or actions. Self-report is the principal means by which one can learn about someone else's experience. Because pain is primarily an internal experience (Merskey and Bogduk, 1994), self-report, when available, is widely considered to be the primary source for assessment and measurement of pain, taking priority over observation, reports by proxies such as family members, physiological data, and knowledge of the clinical context (Pasero and McCaffery, 2011). However, describing self-report as 'the gold standard' is misleading (Craig, 2009; Craig and Badali, 2004). A gold standard score is a score which, in the presence of conflicting data, must be regarded as the correct one. But there are many circumstances under which self-reports of pain may be distorted or misunderstood, as detailed later in this chapter.

In young children such as normally developing 2-year-olds, self-report may be limited to vocalization and pointing to indicate the

presence of pain in parts of their body. Starting around age 3 years, children can learn to quantify the intensity of their pain (small, medium, big) and to describe its location and its temporal and sensory qualities. By early adolescence, the ability to use self-report measures is similar to that of adults.

Complementing this chapter, several other detailed discussions of assessment of paediatric pain by self-report are available (Champion et al., 1998; Cohen et al., 2008; Huguet et al., 2010; Ruskin et al., 2011; Stinson et al., 2006; von Baeyer, 2006, 2009a).

### Background

#### Assessment versus measurement

Measurement is assigning a number to a quantity and is most often done for pain intensity, although other aspects of pain such as its unpleasantness and its temporal features can also be quantified. Assessment is a broader enterprise: collecting and appraising qualitative as well as quantitative information, often from multiple sources, and taking the context into account. Measurement is often part of assessment. Assessment includes appraisal of the developmental, psychosocial, and medical factors that trigger, exacerbate, and relieve the pain.

The purposes of *assessment* include diagnosis of the cause of the pain, selection and evaluation of treatments, goal setting, and allocation of resources such as laboratory investigations. The purposes of *measurement* of pain intensity include quantifying pain before analgesic treatment and evaluating the effects of that treatment, both for individuals and in clinical trials.

#### Domains of assessment

Describing pain only in terms of its intensity is like describing music only in terms of its loudness: it is a gross oversimplification of the complexity of pain experience (von Baeyer, 2006). That oversimplification is needed to make decisions about pain management and to evaluate their outcome. However, numerous other aspects of pain can be assessed by self-report, as reviewed and systematized by the Initiative on Methods, Measurement and Pain Assessment in Clinical Trials (IMMPACT, <<http://www.immpact.org>>). This is a multidisciplinary project to improve clinical trials of treatments

for pain based on expert consensus and commissioned reviews of literature. The paediatric IMMPACT project (McGrath et al., 2008) identifies domains that would be important to assess not only in clinical trials but in many clinical situations. (The word ‘domain’ is used here in the sense used in the adult and paediatric IMMPACT reports, that is, meaning the different aspects or dimensions of pain, including intensity, location, sensory qualities, etc. The word is used with a different sense by Lee and Stevens (Chapter 35, this volume).) Self-report is an important source of information on each one. The domains include, among others, those listed in Table 36.1. The functional measures include measurement of interference caused by pain with physical, cognitive, emotional and social functioning (e.g. school participation and performance), as well as coping.

As shown in Table 36.1, a mnemonic for domains of assessment that is widely accepted and used among emergency and other nurses is PQRST. The mnemonic is represented in many slightly differing forms on the Web, adapted here.

**Table 36.1** Domains of assessment of pain<sup>a</sup>

Ped-IMMPACT	PQRST mnemonic
<ul style="list-style-type: none"> <li>♦ Pain intensity</li> <li>♦ Symptoms and adverse events</li> <li>♦ Physical functioning</li> <li>♦ Emotional functioning</li> <li>♦ Role functioning</li> <li>♦ Sleep</li> </ul>	<ul style="list-style-type: none"> <li>♦ P = Provocation and Palliation. What started the pain? What makes it worse? What makes it better?</li> <li>♦ Q = Quality. What are the sensory qualities of the pain (aching, stabbing, pricking, burning, etc.)?</li> <li>♦ R = Region and Radiation. Where is the pain located? Does it spread?</li> <li>♦ S = Severity. Score the pain intensity using a self-report or observational scale.</li> <li>♦ T = Timing and Type of onset. When did it begin? How often does it occur? Is it sudden or gradual? How long does it last?</li> </ul>
Other	
<ul style="list-style-type: none"> <li>♦ Past pain experiences: surgery, accident, illness</li> <li>♦ Family members’ pain histories and pain behaviour</li> <li>♦ Other pains in addition to the presenting problem</li> <li>♦ For each type of pharmacological, physical, and psychological treatment used in the past: effectiveness, adherence, and adverse effects</li> </ul>	

<sup>a</sup>Ped-IMMPACT refers to the paediatric project of the Initiative on Methods, Measurement and Pain Assessment in Clinical Trials, <<http://www.immpact.org>>. Categories listed under ‘Other’ are particularly relevant to recurrent and chronic pain.

Data on these domains should be recorded in patient charts and flow sheets. A frequent concern, however, is that most flow sheets and electronic medical records allow for only a single number for a pain intensity score (parallel to the boxes for vital signs such as temperature). Thus the domains of assessment might be covered on admission, for example, in an Initial Pain Assessment Tool (<<http://www.partnersagainstpain.com/printouts/A7012AF4.pdf>>), but might not be followed up systematically in subsequent assessments, although information can be placed in narrative notes.

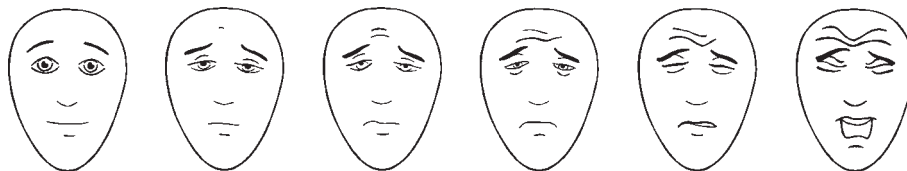

## Age-appropriate measurement of pain intensity

The ability to self-report internal states normally develops starting around age 3 years, with particularly rapid increases in the preschool years (Besenski et al., 2007; Spagrud et al., 2003). This developmental change is illustrated in Figure 36.1, which is based on the assumptions that an age-appropriate self-report tool is used and that children are trained in use of the tool when not in acute distress. The developmental course in this ability is parallel with advances in other language and cognitive skills, and is influenced by experience with pain (von Baeyer et al., 2011).

### Age 8 years and older: visual analogue scale; numerical rating scale

The most commonly administered scale, the numerical rating scale (NRS; <<http://www.usask.ca/childpain/NRS>>), is well supported by recent studies for use in children 8 years and older (Bailey et al., 2010; Miró et al., 2009; von Baeyer et al., 2009). An alternate name for the NRS, when it is administered entirely verbally, is verbal numeric scale (VNS): this name has the advantage of distinguishing the tool from scales administered on paper or electronically. There are no established or validated verbal descriptors for the maximal pain on the NRS or VNS (e.g. most hurt, worst pain, worst possible pain, most pain you could imagine), but these anchor phrases have a marked influence on pain intensity scores (von Baeyer, 2009b). Moreover, intermediate numbers have no fixed meaning across individuals: a 6 out of 10 might mean moderate pain for some people and severe for others. Difficulties often encountered with the VNS include using numbers above the top of the scale and reporting fractional numbers. Reduction of these difficulties has been achieved for adults by showing the patient a visual aid, that is, a printed page showing the numbers from 0 through 10 with verbal anchors at each end (Pasero and McCaffery, 2011) while requesting a verbal response.

The visual analogue scale (VAS) is a well-established tool for obtaining self-report of pain intensity in normally developing children 8 years and older (Stinson et al., 2006), with some studies suggesting that it can be used for younger children in the 5 to 7-year age range. Variants of the VAS have been explored, notably the coloured analogue scale (McGrath et al., 1996) which has been extensively validated and used in research.

**Figure 36.1** Faces Pain Scale—Revised (FPS-R). Instructions in about 40 languages are available at <<http://www.iasp-pain.org/FPSR>>. Reproduced from Hicks et al., The Faces Pain Scale—Revised: toward a common metric in pediatric pain measurement, *PAIN*, Volume 93, Issue 2, pp. 173–83, Copyright © 2001. This figure has been reproduced with permission of the International Association for the Study of Pain® (IASP). The figure may NOT be reproduced for any other purpose without permission.

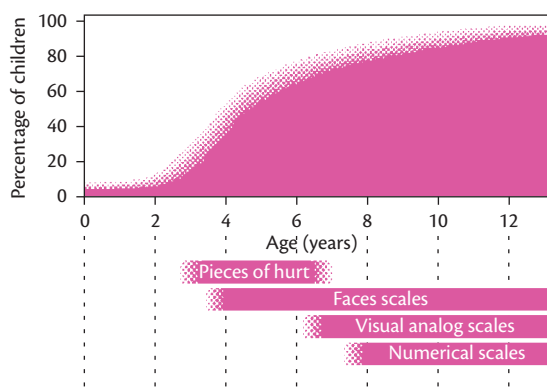

For quick use, or for individuals who have difficulty with these scales, simple word descriptors of intensity sometimes suffice: for example, 'a little bit' of hurt, 'medium', 'a lot', 'a real lot' for young children, or 'slight', 'mild', 'moderate', 'strong', and 'intense' for older children (Ruskin et al., 2011, p. 231). No standardized sets of these words have been evaluated and they cannot be recorded on the popular 0 to 10 common metric for pain intensity scales. Similarly, for informal use, the rapid and simple finger span scale is available: pain intensity is indicated by the distance between the tip of the thumb and the tip of the index finger (Merkel 2002) with more space signifying more pain. The finger span scale has the advantages of requiring no equipment, nor speech by the child, though the scale may be psychometrically inferior to faces and visual analogue scales (Goodenough et al., 2005).

As represented in Figure 36.1, some normally-developing individuals over the age of 12, including perhaps 8% to 10% of adults, find that pain intensity scales such as NRS and VAS do not make sense to them, and thus cannot make use of these tools, reflecting the complex and idiosyncratic nature of pain scales (Williams et al., 2000).

### Age 3 years and older: faces scales, Pieces of Hurt

The VAS and the NRS are presumed to require the child to have some competence in seriation (putting things in order) and magnitude estimation, as well as counting in the case of the NRS. These skills are not well developed in most children before age 6 or 7. By contrast, faces scales, in principle, require only matching one's own state of distress to one of the pictures, without necessarily having to estimate quantities along a numerical or spatial dimension (Champion et al., 1998). These limited cognitive demands make faces scales more suitable for children of preschool age than the VAS and NRS.

Dozens of faces scales have been created; of these, three have emerged as the predominant and best validated choices (Tomlinson et al., 2010): the Faces Pain Scale–Revised (FPS-R; Figure 36.2; <<http://www.iasp-pain.org/FPSR>>) (Hicks et al., 2001); the OUCHER (Beyer et al., 1992; <<http://www.oucher.org>>); and the Wong-Baker FACES Pain Rating Scale (Whaley and Wong 1991; <<http://www.wongbakerfaces.org>>). Each of these was developed

**Figure 36.2** Estimated percentage of children who are able to provide valid self-report of pain intensity as a function of age.

Adapted from Lara Spagrud et al., *Children's Self-Report of Pain Intensity: The Faces Pain Scale–Revised*, *American Journal of Nursing*, Volume 103, Issue 12, pp. 62–64, Copyright © 2003 C. L. von Baeyer, with permission of the author. This figure has been reproduced with permission of the International Association for the Study of Pain® (IASP). The figure may not be reproduced for any other purpose without permission.

independently starting in the 1980s. Each has six faces and is scored 0–2–4–6–8–10, using the widely accepted 0 to 10 common metric (von Baeyer and Hicks, 2000). The scales are otherwise quite different from each other. There has been debate over the psychometric properties, utility, and preference among these three faces scales (e.g. Chambers and Craig, 1998). The FPS-R has most often been recommended as the scale to use in research due to its explicit interval scale properties, its neutral rather than smiling lower anchor, its lack of tears at the upper anchor, its validation in several countries, and the availability of instructions in many languages (Tomlinson et al., 2010).

The Pieces of Hurt tool comprises four poker chips, checkers, or similar game pieces (Hester 1979). Children are asked to indicate how many 'pieces of hurt' they have, from 0 to 4 years. Various sets of instructions have been published. The tool was originally referred to as the Poker Chip Tool but this has elicited some resistance from parents who do not want their child exposed to gambling, so the more acceptable phrase 'Pieces of Hurt' is commonly used. Although the research on this tool has been done primarily with 5- and 6-year-olds, it has been recommended for use with children as young as 3 years (Stinson et al., 2006).

Other simplifications of pain intensity scales adapted for preschool-aged children have been proposed but not yet adequately studied. For example, one could ask whether the child has any hurt (using a word the child knows). If the answer is no, the score is 0. If yes, then a modified faces scale comprising three faces—small, medium, and large pain intensity—is administered (von Baeyer et al., 2011, 2013). The faces would be redrawn to suit the preference and comprehension of young children.

### Interpretation of self-reported pain intensity scores

In general, comparisons of pain intensity scores across time within an individual are more valid than comparisons of such scores across different children. In other words, the score 8/10 might mean something quite different to one child than to another. However, within individuals, an increase or decrease over time can be interpreted as an index of the efficacy of pain management efforts.

Despite these limitations in interpretation of self-report scores, there have been efforts to create and validate algorithms governing analgesic administration by pain scores, whereby drugs and dosages are selected following rules based on the intensity and duration of pain (e.g. Falanga et al., 2006). Data on effects of such algorithms are mixed.

Children's pain intensity scores do not always make sense to adults. Children sometimes assign high scores to their pain intensity when they are assumed to be in no or little pain (e.g. before a needle or operation); at other times they assign low scores when they are believed to be in severe pain. Caregivers might not understand the numerous possible reasons for these discrepancies.

- ♦ Young children might not understand the scale, so they often use a variety of irrelevant strategies to answer the caregiver's question (von Baeyer et al., 2009). For example, up to one-third of children aged 3 and 4 use only the bottom and top of pain scales, treating them as dichotomous (pain or no pain) rather than graded scales.
- ♦ A variety of cognitive skills are required for accurate use of self-report scales, as catalogued by Besenski et al. (2007). These skills

develop gradually, with a majority of children but not all acquiring the necessary skills by age 7 or 8.

- ♦ Children sometimes locate their pain within a body part, not in themselves, thus in a sense separating themselves from the pain and producing lower than expected pain ratings (Wennstrom and Bergh, 2008).
- ♦ Adults have experience with a variety of mental models (Halford, 1993) for rating quantities. They have encountered volume controls to adjust loudness; thermometers, weight scales, and rulers; and star systems for rating quality of hotels or movies. Young children have far less experience with such mental models, though they have encountered staircases (low to high steps), toys that can be placed in order from small to large, and pictures of small and larger numbers of objects. Such analogies can be useful in measurement of pain intensity, as for example in the Pieces of Hurt tool.
- ♦ Children probably have a very different understanding of the top scale anchor (a hypothetical maximal level of pain) than adults, as children have less direct and vicarious experience of severe pain. Moreover, young children might not be able simultaneously to think of their own pain and a hypothetical maximal pain for comparison of the two, a characteristic termed 'centration' in Piaget's accounts of cognitive development (Gelman and Baillargeon, 2003).
- ♦ Children might be inclined to deny or minimize their pain because they believe, accurately or not, that something bad will happen as a result of giving a high score, e.g. having to undergo further unpleasant diagnostic procedures, or disappointing their family, or not being allowed to do a desired activity.
- ♦ Children might be motivated to provide high pain intensity scores because they anticipate some benefit, e.g. being allowed to stay home from school, or avoiding chores, or eliciting increased parental care and concern, or obtaining desired medications.

When a child's self-report pain scores do not seem to make sense to the caregiver, additional efforts to resolve discrepancies are needed, as discussed in the following sections.

### The place of self-report in a hierarchy of pain assessment techniques

Pasero and McCaffery (2011, p. 123) present a five-step strategy for assessment that starts with (1) eliciting self-report if possible. If the patient is unable to give a self-report, then the following steps are followed in order. (2) Identify pathological conditions and events or procedures that might cause pain. (3) Observe for behaviours expressing pain, possibly using an observational tool. (4) Solicit information from caregivers and family members. (5) Attempt a trial of physical, psychological, and/or pharmacological means of pain relief, to see if the observed behaviours reflect reduced pain.

### Interpreting self-report scores when they conflict with observation and context

A child might give a low self-report pain score when the context and the child's behaviour suggest that pain intensity is high, or the converse (see case example). The correlation between self-report and observational scales of pain intensity in children is usually statistically significant but modest. For example, in a study

of postoperative pain in children aged 3 to 7 years (Beyer et al., 1990), the median correlation between concurrent scores on an observational measure, the Children's Hospital of Eastern Ontario Pain Scale (CHEOPS), and the Oucher was  $r = 0.41$ , and between the CHEOPS and a mechanical VAS it was  $r = 0.35$ . Similarly, in a study of 5-year-olds undergoing immunization injections (Cassidy et al., 2001), Spearman correlations between a faces pain score and the CHEOPS during and after the needle were  $r_s = 0.47$  and  $r_s = 0.33$ . In other words, in many cases the self-report scores were at variance with observers' scores on a well-established behavioural measure.

The modest observer-child concordance, and the lack of a gold standard measure of pain intensity, lead to a dilemma for clinicians. There is no validated way to combine and balance estimates of pain intensity from different sources, nor to adjust self-report scores to bring them into line with observation and knowledge of the clinical context. Yet several studies have shown that nurses often do so: they alter patients' self-reported pain scores when recording them in medical charts (Pasero and McCaffery, 2011, p. 18), or fail to ask for self-report and substitute their own informal rating. Pasero and McCaffery suggest that when patients' self-report scores are not accepted and acted upon, 'chaos quickly ensues' (p. 21) because each clinician has different impressions, standards, and biases in judging patients' pain. On the other hand, sometimes self-reports conflict with other sources of information (see case example). In this case example, much additional information is required beyond the simple pain intensity score.

One source of the difficulty is the campaign to treat pain scores, particularly self-report pain scores, as the 'fifth vital sign.' In practical terms, that means recording a single pain intensity score similar to a temperature, blood pressure, or heart rate score. Unlike the true vital signs, such pain scores represent a massive oversimplification. To make valid decisions about pain management requires a variety of additional information. Berde and McGrath (2009) stated that 'it remains a clinical art to combine patients' reports, behavioral observation, and physiologic measurement with the history, physical exam, laboratory information, and overall clinical context in guiding clinical judgments and therapeutic interventions' (p. 474). An example of a situation evoking the need for skill in this 'clinical art' is outlined in the case example.

#### Case example: an implausible self-report pain score

*Clinical question:* a 6-year-old male patient has emerged from anaesthesia following hernia repair and is being prepared for transfer to the paediatric ward. The intraoperative anaesthetic is presumed to be past its half-life at this time. The patient's body is rigid in an antalgic position (legs drawn up), he is whimpering, and he has a high heart rate. His facial expression appears to express strong pain. He is shown a faces scale to obtain his self-reported pain intensity. He points to the no-pain (0/10) face. Should this be accepted as indicating that he has no pain, leading to a decision to defer or minimize analgesic treatment?

*Interpretation:* the self-report score of 0/10 in this instance cannot be regarded as 'the gold standard,' that is, a score which, in the presence of contradictory information, must be taken as correct. The self-report conflicts with (1) knowledge of the clinical

context, namely, the fact that the child has had an operation which in most individuals produces pain, and the fact that the intraoperative analgesic is likely to be wearing off; and with (2) observation of his behaviour, including his facial expression, vocalization, and physical rigidity. Alternate explanations for the 0/10 score include the following: the child (1) did not understand or fully attend to the faces scale, or (2) did not want to upset his parent by reporting pain, or (3) was afraid of having to stay in hospital longer, or of having something painful done such as an injection if he admitted to pain on the faces scale.

*Good clinical practice* would be to continue the assessment process as follows. (1) Ask the parents to assist with assessment based on pain behaviours they have noted in their child in the past. (2) Note the child's response to his parents' efforts to distract or comfort him. (3) Administer intravenous analgesia and note the response after an appropriate interval (analgesic trial). (4) Make notes in the medical record of this information, not only a pain score but also the narrative of additional information, for transfer with the patient to the ward. (5) Recommend that a ward nurse or parents discuss the pain scale with the child later on when he is in less distress, so that he can use the scale in subsequent pain management.

### Temporal characteristics of pain

It is common to ask for ratings of pain 'right now' or at the time of a painful procedure, in addition to ratings of pain intensity 'at its worst' and 'at its least' over a specified time period. Particularly with recurrent and chronic pain, questions are needed to assess the frequency and duration of pain episodes: 'How often did you have this kind of pain in the last week/month?'; 'How long did this pain usually last each time you had it?'. More reliable answers to these questions can be obtained via self-report pain diaries, discussed later in this chapter.

### Pain interference

Measures of pain interference assess the extent to which pain impairs child and family quality of life, attendance and performance at school, leisure and social functioning, maintenance of positive mood and mental attention or concentration, and other variables reflecting general functioning. These are relevant both to acute pain (e.g. interference with postoperative ambulation) and chronic pain. An example of such a measure is the brief eight-item PROMIS Pediatric Pain Interference Scale (Varni et al., 2010), which contains items such as 'I had trouble moving around when I had pain' and 'it was hard for me to pay attention when I had pain'. (For further information see Tham et al., Chapter 41, this volume.)

### Comfort-function goal: setting a target level of pain

With children older than about 8 to 10 years, it may be helpful in making decisions on analgesic administration to inquire about the highest severity of pain that would still allow the patient to carry out valued activities (e.g. socializing, exercising, or attending school). The question itself communicates that pain relief might not be complete, and that the patient has a role in balancing the desired effects of medications with their side effects. For example, a child might have severe current pain of 8/10, requiring intervention, but might feel able to go to school when a target pain severity

of 3/10 can be achieved. However, there appears to be no research with children and adolescents on their understanding and utilization of comfort-function goals.

### Location of pain

Patients, including children, often fail to report parts of the body that hurt besides the primary presenting problem or the operative site, so specific inquiry is recommended. For example, children in the postoperative period are sometimes more bothered by an intravenous catheter than by pain at the site of the operation. Self-report of the location of pain can be elicited by verbal questioning, or by asking the child to point to the affected parts, or by providing a checklist of body parts, or by utilizing a body diagram (also referred to as a pain chart, manikin, or pain drawing). The latter methods are reviewed by von Baeyer et al. (2011). Research presently available supports the ability of most children age 8 years and over to complete a pain chart unassisted, while younger children may be able to do so with adult support. Also promising for locating pain symptoms in younger children are picture boards as used in assistive and augmentative communication with children with handicaps; these require only pointing to one among an array of pictures (Mesko et al., 2011).

### Pain qualities

Sensory characteristics of pain, such as burning, aching, or pricking, may be of diagnostic importance, particularly in differentiating neuropathic from nociceptive sources of pain. The Adolescent Pediatric Pain Tool (Savédra et al., 1993) includes a list of adjective descriptors for this purpose, adapted from the McGill Pain Questionnaire. The list includes words such as: annoying, bad, horrible (among affective descriptors); crushing, itching, burning (among sensory descriptors); comes and goes, constant (among temporal descriptors). Patients are asked to circle the words that apply to their pain. It is designed for children age 8 and over.

### Desirable features of self-report measures of pain

Tools for collection of self-report should have as many as possible of the features listed in Box 36.1 (Hester et al., 1998; Pasero and McCaffery 2011; von Baeyer 2006). The self-report scales recommended in this chapter have most or all of these characteristics.

### How are self-report measures validated?

Validation of self-report measures is inherently problematic because self-report reflects internal experience that is not accessible by other means. Articles about pain assessment often describe a scale simply as 'reliable and valid'. This reflects a misunderstanding of the nature of validation, which is not a one-time occurrence but a gradual process of accruing and weighing evidence for the ability of the scale to make accurate predictions or discriminations in a variety of clinical contexts and with different clinical populations. In systematic reviews, a scale is generally considered adequately validated for research and clinical use in a particular context if multiple studies of good methodological quality from different research groups have demonstrated one or more types of validity for that context.

Several lines of evidence are commonly used to establish that a pain scale is reliable and valid for a particular clinical application

**Box 36.1** Desirable features of self-report measures of pain

- ♦ Evidence for validity and reliability in the current clinical context.
- ♦ Developmentally and culturally appropriate, that is, within the child's cognitive, language, and social skills.
- ♦ Easily and quickly understood, and well accepted by patients and clinicians.
- ♦ Easily used with the patient to set pain management or functional goals (e.g. use the scale to indicate a target pain intensity as a guide for pain management or for planning physical exercise).
- ♦ Places low burden on clinician to administer, score, and record.
- ♦ Free or inexpensive and easy to obtain, reproduce, and distribute (e.g. on the Internet).
- ♦ Where physical materials are needed, these should be easily disinfected or disposable.
- ♦ Available in multiple languages.

Source: data from Pasero and McCaffery, *Pain assessment and pharmacologic management*, Elsevier Mosby, St Louis, Missouri, USA, Copyright © 2011, and Hester et al, Putting pain measurement into clinical practice, in *Measurement of pain in infants and children* (ed.) Finley and McGrath, International Association for the Study of Pain Press, Seattle, USA, pp. 179–198, Copyright © 1998.

**Box 36.2** Lines of evidence for validity of pain scales. Examples of studies employing each line of evidence to support self-report measures of pain intensity are cited by von Baeyer (2006)

- ♦ Correlations (or similar measures of association) of self-report ratings with other validated self-report scales administered at the same time. Such validity correlations are typically high, and it is good practice to set an a priori minimum such as  $r \geq 0.7$  in validating a new scale. (Simply indicating statistical significance is not adequate, because in large samples very small associations are statistically significant but are not meaningful indications of validity.)
- ♦ Correlations (or similar measures of association) of self-report ratings with validated observational pain scales administered at the same time. These correlations are typically moderate, and it is good practice to set an a priori minimum such as  $r \geq 0.4$  in validating a new scale.
- ♦ Accurate ranking of hypothetical no pain, moderate-pain, and high-pain events depicted in pictures or stories.
- ♦ Increased pain ratings in response to painful clinical or experimental procedures.
- ♦ Decreased pain ratings in response to analgesic interventions or less painful ways of performing a procedure.
- ♦ Decreased pain ratings over successive minutes, hours, or days of postprocedure, postoperative, or postinjury recovery.

(Box 36.2). Validity of assessment tools is best demonstrated by multiple lines of evidence from multiple research groups in multiple and diverse clinical samples, as compiled in systematic reviews (e.g. Cohen et al., 2008).

**Children with mild developmental delay or communication impairment**

Estimation of pain intensity in children with moderate to severe neurological impairment relies primarily on observational measures (see Belew et al., Chapter 16; MacLaren Chorney and McMurtry, Chapter 37, this volume). Few studies have examined self-report measurement in this population (Benini et al., 2004). Children with mild impairment, or a mental age above 4 years, can sometimes use self-report measures designed for young children (Fanurik et al., 1998). However, nurses often overestimate the ability of cognitively-impaired children to use self-report scales (Fanurik et al., 1998). Children with mild cognitive impairment should, in general, be given a chance to use self-report scales suitable for their mental age, and the resulting scores can be supplemented or supported by observational measures.

**Measurement in chronic versus acute pain**

Self-report assumes special importance in chronic and recurrent pain, because the overt behavioural expressions of pain attenuate over time without necessarily being associated with decreases in the internal experience of pain. In other words, patients with chronic pain commonly report high levels of pain without showing overt expressions of pain, unless the latter are triggered by social or physical cues. Assessment of chronic pain includes an emphasis on its consequences, including physical, emotional, and social functioning, thus requiring multidimensional pain questionnaires and interview protocols.

Multidimensional pain scales, that is, scales that measure different dimensions, domains, or aspects of pain at the same time, are used mostly with recurrent and chronic pain conditions. Such scales are available in both self-report and parent-report forms, including the Varni/Thompson Pediatric Pain Questionnaire (Varni et al., 1987) and the Bath Adolescent Pain Questionnaire (Eccleston et al., 2005). The Adolescent Pediatric Pain Tool (Savendra et al., 1993) similarly provides a body outline, a rating scale for pain intensity, and a checklist of descriptive words. Self-report measures of pain have also been published for some specific recurrent and chronic disorders such as abdominal pain (Malaty et al., 2005) and headache (Budd et al., 1994).

Tools to elicit self-reports of pain intensity are generally similar for acute and chronic pain. Pain diaries are used to track fluctuations in pain intensity, interference and coping over time (Palermo, 2009; Stinson, 2009).

**Gender and cultural issues**

While sex differences are widely reported in the prevalence and intensity of pain, no studies to date suggest that pain must be assessed using different methods in boys versus girls. The most salient sex difference in the pain assessment process reported to date may be the ability of girls to discriminate between pain intensity and pain unpleasantness at a somewhat younger age (around 8 years) than boys (around 10 years) (Goodenough et al., 1999).

By contrast, much research has focused on adaptation of self-report tools to different cultural, ethnic, or racial groups. Commentary on pain assessment in sub-Saharan Africa is provided by Walters (2009). One of the best-known faces scales, the OUCHER, is published in separate versions displaying Caucasian, African American, Hispanic, Asian, and First Nations (North American Aboriginal) children. The Faces Pain Scale–Revised and the Wong-Baker FACES Pain Rating Scale have both been used around the world; psychometric studies on the FPS-R have been carried out in Australia, Brazil, Canada, Spain, Thailand, and USA. Inuit children and adolescents in the Canadian Arctic prefer the standard Wong-Baker FACES Pain Rating Scale to a version with pictures adapted for the Inuit culture, although older adults prefer the latter (Ellis et al., 2011). The three most-researched faces scales appear to have acceptable utility in many cultures and countries.

### Self-report using new technologies

Rapid development is occurring in the use of smart phones, computers, and web-based applications to elicit, record, and analyse self-reports of pain (Stinson, 2009; Stinson et al., 2008). Documented advantages of such technologies include the following.

- ♦ In numerous studies, adolescents and children as young as 4 years prefer computer over paper-and-pencil measures. For example, in a study of hospitalized children, 87% of those who expressed a preference preferred a handheld computer over paper for administration of the Faces Pain Scale–Revised (Wood et al., 2011).
- ♦ These technologies reduce the burden on caregivers in administration and scoring of measures.
- ♦ They reduce or eliminate backfilling, that is, the common tendency for people to skip diary entries and then fill them in later.
- ♦ They lend themselves to integration in electronic medical records (EMR) and automated databases: scores can be uploaded automatically using Web or cell phone communication. A caveat in this context is that EMR systems often provide only a single data field for a pain score at a particular time point in time, making it difficult to deal with (a) discrepant estimates from different sources (self-report, parent observation, staff observation, clinical context), and (b) multiple ratings over time that come from a pain diary.

### Future research on self-report

It is generally assumed that assessing pain using pain scales improves pain management outcomes, but evidence supporting this assumption is scant (Franck and Bruce 2009). Further research is needed on this topic, as discussed by Lee and Stevens (Chapter 35, this volume).

While the NRS is now well established for children 8 years of age and older, the validity and reliability of this tool in the hands of younger children who can count, at least by age 6 and 7, require further investigation (Castarlenas et al., 2013).

Preschool-aged children, 3 to 5 years of age, are often not asked for self-reports because their responses, even on simple pain intensity scales, are frequently eccentric and hard to understand (Champion et al., 1998; von Baeyer 2006). Moreover, asking questions is thought to be a poor way to get information from young children, especially for strangers (Wilkinson 2003). Instead, it takes extra time and special skill to interact with young children in order

#### Box 36.3 Recommendations for clinical practice, education, and research

- ♦ Use self-report measures as the *primary source* in a hierarchy of pain assessment methods (Pasero and McCaffery, 2011) (followed by consideration of probable sources of pain, observation of behaviour, obtaining parents' report of pain behaviours, and conducting a trial of pain-relieving treatment.).
- ♦ To the extent that the clinical situation requires and permits, obtain self-report on all of the relevant domains of assessment (see Table 36.1).
- ♦ Obtain and record the child's self-report of pain intensity, location, and temporal and sensory features on initial assessment and at intervals following treatment.
- ♦ For measurement of pain intensity, use a validated scale, e.g. the NRS from age 8 up, one of three faces scales from age 4 up, or the Pieces of Hurt for age 3 to 6.
- ♦ Use consistent verbal anchor phrases for maximal pain, such as 'most pain' or 'worst pain you could have,' without embellishment or variation between patients.
- ♦ For children with mild developmental delay, use self-report measures suitable for their mental age.
- ♦ Compare pain intensity scores across time within individuals, not across children, because the scores have different meanings for different people.
- ♦ Institutions should select a small set of scales for regular use by staff that covers the range of ages and clinical conditions typically encountered. Such a set might include NRS for older children, a faces scale for younger children, and one or two appropriate observational scales. For chronic pain, one or two multidimensional questionnaires or interviews should be selected.
- ♦ Remember that pain assessment is more than measurement of intensity: location, temporal, sensory and emotional features, and functional consequences of pain also require assessment.
- ♦ Take self-reports of pain into account when planning pain treatment and evaluating its effects.

to develop an 'ideal discourse' in which the children's thoughts can be expressed without fear of giving a 'wrong answer' or being judged or criticized. The social and cognitive barriers to effective communication with preschool-aged children about pain, and targets for research on these issues, are discussed by Champion et al. (1998).

### Key recommendations

Recommendations for clinical practice, education, and research on self-report assessment of pain in children are offered in Box 36.3.

### Conclusion

Self-report is the primary source of information for assessment and measurement of pain, to be obtained whenever possible. But

getting valid self-reports from children presents special challenges, particularly those younger than 6 to 8 years.

This chapter has emphasized interpretation of the meaning of self-report scores in the context of many biological, social, cognitive, and developmental influences. Tools suited for different ages are cited. An agenda for future research is suggested.

Self-reports of pain can be compared within individuals across time, but not between individuals. Their meaning is often idiosyncratic and may not agree with estimates of pain intensity based on other sources, that is, observation of behaviour and knowledge of the clinical context. This chapter concludes with a structured process to follow when self-reports of pain or the absence of pain are not supported by information from other sources.

## CHAPTER 37

---

# Behavioural measures of pain

Jill MacLaren Chorney and  
C. Meghan McMurtry

### Introduction

Measurement is the process of assigning numbers to things (Bakeman and Gottman, 1986) and can be as familiar as using a ruler to measure length and a scale to measure weight. We also use measurement to characterize internal states and experiences. In the context of pain, we can use numerical or facial expression scales to translate one's own or another's experience into a given value. Using behavioural tools, we seek to measure, or assign numbers to, observable behaviours. Behaviours that are measured may be motoric (body movements), vocal (sounds), or verbal (words) and observed behaviours can be further characterized (e.g. tone of voice, intensity of movement).

This chapter will review the current state of evidence on behavioural measures of pain in children and adolescents including a brief discussion of future directions. To demonstrate the utility of behavioural scales, we also include a clinical case example at the end of this chapter. A few limits of coverage should be noted. First, although some of the measures included in this chapter may have been used for infants, we will not review measures that are only validated for infants as these measures are covered by Lee and Stevens (Chapter 35, this volume). Second, given that there are no well-established behavioural measures of chronic pain, this chapter will focus on measures that are relevant to acute and procedural pain and will also not cover other pain-related outcome measures (e.g. functional disability, quality of life). Finally, multidimensional composite scales containing behavioural and physiological items will not be reviewed (e.g. COMFORT; Ambuel et al., 1992). There are recent, good quality reviews published in the area of behavioural measures of pain (Cohen et al., 2008; von Baeyer and Spagrud, 2007). As with any assessment tool, the psychometrics of behavioural measures are critical; thus, tools deemed well established or approaching well established in these reviews will be included. Coverage of tools that are not well established can be found in the relevant reviews (Cohen et al., 2008; von Baeyer and Spagrud, 2007). We make one notable exception: the existing reviews did not specifically identify measures that are relevant to children with developmental delays or cognitive impairments. We see measures for this population as particularly important and therefore include a brief review here.

### Background

#### Why use behaviour as a measure of pain?

Given the subjective and personal nature of pain, self-report has generally been considered to be the gold standard of measurement. Despite the recognition of its importance, in some cases self-report may not be feasible, possible, or the best choice for measuring pain (Schiavenato and Craig, 2010). For example, children who do not communicate verbally or who have cognitive impairments may have difficulty providing self-report. Children who are sedated or in severe distress may also have difficulty providing self-report and behavioural observation is less intrusive. Even in situations in which self-report is possible, other forms of measurement may be beneficial. For example, in some cases children may be motivated to under-report their pain to appear brave or to avoid receiving needles. In these cases, observing behaviour as a measurement of pain may be helpful in determining whether the child is in need of further assessment or treatment. In fact, a child's behaviour may be the first signal to a caregiver that the child is in pain (McGrath, 1998). Observation of behaviour is also particularly useful when the goal is to examine interactions between individuals and understand the bidirectional relationships between the social context and experience of pain (Schiavenato and Craig, 2010).

#### Characteristics of behavioural measures

Behavioural measures may vary on several dimensions, including the level of granularity with which they capture observations. At one end are global measures of pain such as numerical rating scales or visual analogue scales. These scales are clinically-feasible, but individual behaviours determining the score may not be well understood and children demonstrating very different behaviours may be given the same rating (von Baeyer and Spagrud, 2007). In contrast to global measures are those that characterize behaviours at a very precise level such as the Child-Adult Medical Procedure Interaction Scale (Blount et al., 1989). These systems are useful, but are time consuming to administer and generally require high-quality video recordings of behaviours.

Behavioural measures also vary based on whether they characterize the intensity and/or frequency of behaviours. Measures can be categorized as dichotomous (present/absent), ordinal (more, less), and interval (frequency over time). Although easiest to collect, dichotomous checklists are limited in the extent to which they capture gradations of behaviour and infer intensity from number of behaviours endorsed in a given time period. Rating scales are more specific with scores usually considered on Likert-type scales (e.g. none/absent, a little, frequently). Interval scales generally capture data over time and can vary in their level of specificity.

Time sampling may also vary. Some measures are designed to record behaviours at one point in time, but in this way capture only a snapshot of a child's behaviour. Other measures define an observation interval that may be based on time (e.g. 15 sec, 24 h) or event (e.g. phase of procedure). This method captures a longer sample of children's behaviour but risks distortion. For example, in a 24 h observation interval, a child who cries for only 30 min receives the same score as a child who cries for the entire period. Continuous recording is also sometimes used. In this method of recording, observers note any instance when a behaviour occurs; this coding allows various metrics including proportions of behaviours (e.g. target behaviour/total behaviours), proportions of time (e.g. behaviours/time interval), or rates (e.g. behaviours/minute) of behaviours. Continuous recording can also be used to report information on timing of when behaviours occurred (time-sequential) or simply the order of behaviours (event-sequential). Continuous recording provides the most representative data, but is time intensive to collect, although this has been made easier with recent advances in computer recording.

An understanding of differences between behavioural measures is critical and the previous list of characteristics (e.g. granularity, time sampling) is intended to be illustrative rather than exhaustive. There is no measure that is perfect for all situations; each type of measure has its own strengths and weaknesses and these are important to acknowledge and understand when choosing a scale to use and interpreting resulting data.

## Behavioural measures of pain in children

Measures reviewed are organized based on the context in which they have been typically used (e.g. procedures, postoperative). Consideration is given to the time and equipment requirements for each of these measures. For example, several of the measures require video recording, training, and detailed coding and, although they offer important information for research, they may not be practical in clinical settings due to high burden. Alternatively, some measures can be administered in the moment while behaviour is occurring and therefore are more feasible in clinical settings. Further discussion is also provided regarding the type of rater who administers these scales. Tables 37.1 and 37.2 provide an overview of reviewed measures including original reference and context.

### Procedural or brief pain episodes

#### Children's Hospital of Eastern Ontario Pain Scale (CHEOPS)

The CHEOPS (McGrath et al., 1985), originally developed to measure postoperative pain, has been used in a variety of painful contexts and is now considered a well-established measure of brief pain episodes (Cohen et al., 2008; von Baeyer and Spagrud, 2007). The CHEOPS is administered using a time-sampling procedure with a

5 sec observation period and a 25 sec recording period (McGrath et al., 1985). In some protocols, this sampling procedure has been repeated four times over a 2 min period and an average of scores has been used (Beyer et al., 1990). The CHEOPS consists of six items each rated on a three-point scale (e.g. cry ranges from 1 = no cry to 3 = scream), with total scores ranging from 4 to 13 points for each period. Although the initial validation of the scale did not provide descriptors for ranges of scores, subsequent researchers have done so. For example, Disma and colleagues (2009) described scores between 4 and 6 as minimal pain, 7 to 9 as mild pain, and 10 to 13 as severe pain. The CHEOPS was designed to be clinically feasible and can be completed relatively quickly.

The CHEOPS was developed using nurses' reports of common behaviours exhibited by post-surgical children (McGrath et al., 1985). After piloting and refinement, the scale showed excellent initial interrater reliability (average per cent agreement ranged from 90% to 99.5%) and good internal consistency (inter-correlations among items ranged from 0.35 to 0.81). Convergent validity was demonstrated with moderate to high correlations with nurse and researcher-completed (unblinded) visual analogue scale ratings (total score correlations of 0.81 and 0.86 respectively) (McGrath et al., 1985). CHEOPS scores were also responsive to analgesic intervention (although ratings were unblinded). Subsequently, comparison of the CHEOPS with two self-report measures of pain demonstrated that scores on the CHEOPS tend to underestimate pain over time after surgery (Beyer et al., 1990). To date, the CHEOPS has been used extensively in a variety of painful contexts (e.g. surgery, immunizations, venepunctures, fracture reduction) and countries.

#### Face, Legs, Activity, Cry, and Consolability scale (FLACC)

The FLACC (Merkel et al., 1997), originally developed for post-operative pain, has been classified as a well-established measure for both postoperative and brief pain episodes (von Baeyer and Spagrud, 2007). Although based in part on behaviours contained in the CHEOPS, each of the five behaviours on this scale is scored on a consistent 0 to 2 metric, yielding a total score between 0 and 10 with higher scores indicating greater pain. The FLACC is used as a point assessment, although the observation period has not been specified. It was designed to be clinically-feasible with low burden. Despite the 0 to 10 metric, it should be noted that, as the interval properties of the tool have not been firmly established, the score cannot be considered equivalent to a 0 to 10 self-report scale (von Baeyer and Spagrud, 2007).

The original study of the FLACC (Merkel et al., 1997) showed adequate interrater reliability (average  $r = 0.94$  for 30 children at three separate time periods; kappa values for each FLACC category were acceptable and ranged from 0.52 to 0.82). Supporting convergent validity, a moderate correlation ( $r = 0.41$ ) was found between the FLACC scores and a global nurse rating of pain and a strong positive correlation ( $r = 0.80$ ) was found with another measure of pain (Objective Pain Scale). The FLACC also demonstrated responsiveness to analgesic intervention (albeit with unblinded raters) (Merkel et al., 1997). Subsequent research has continued to support the interrater reliability, construct validity, internal consistency, specificity and sensitivity of the FLACC (Voepel-Lewis et al., 2010). Since its development, the FLACC has been used in a variety of different acute pain contexts (Bable et al., 2009) and age ranges (Marmo and Fowler, 2010). Several language translations

Measure	Rater	Number and format of items	Behaviours included	Scoring method	Scoring details
NCCPC	◆ Primary caregiver	◆ 30 items all dichotomously scored	Seven subscales: ◆ Vocal Behaviour (e.g. whining) ◆ Social (e.g. withdrawn) ◆ Facial Expression (e.g. grimacing) ◆ Activity (e.g. less active) ◆ Body and Limbs (e.g. stiff, spastic) ◆ Physical signs (e.g. change in colour) ◆ Eating/Sleeping (e.g. increase in sleep)	◆ Interval scoring ◆ Interval time not defined	Range: 0–30
NCCPC-Revised	Primary caregiver	30 items all rated 0 to 3	Same as original NCCPC	◆ Interval scoring ◆ Interval time not defined	Range 0–90
NCCPC-Postoperative	Primary caregiver or researcher	6 subscales with items rated 0–3 each	Same as original NCCPC with Eating/Sleeping scale removed	◆ Interval scoring ◆ 10-min interval	Range 0–60

**Table 37.2** Review of original references for behavioural measures of pain

Measure	Primary reference	Population	Context
CHEOPS	McGrath et al. (1985)	<i>Original:</i> 1–7-year-old Canadian children	<i>Original:</i> post-surgical (variety of surgeries)
		<i>Subsequent:</i> Age range has included 4 months–18 years	<i>Subsequent contexts have included:</i> perioperative (anaesthesia induction, post-surgical); various medical procedures (acupuncture, venepuncture, intramuscular injections, immunizations, fracture reductions, dental, bone marrow aspirations, laceration repair); severe pain from fractures or sickle cell disease
		<i>Samples have included:</i> American, Canadian, Chinese, Czech, Dutch, French, Indian, Iranian, Italian, Korean, Scottish, Singaporean, Spanish, Swedish, Turkish, Thai, and Trinidadian children and adolescents	
FLACC	Merkel et al. (1997)	<i>Original:</i> 2-month–7-year-old American children	<i>Original:</i> post-surgical in the PACU
		<i>Subsequent:</i> Age range has included 15 days to adults over 80 years	<i>Subsequent contexts have included:</i> perioperative (including post-dental surgery); critically ill, ventilated and minimally conscious individuals; various medical procedures (e.g. immunizations, urethral catheterization, temperature assessment, nasogastric tube insertion, venepunctures or subcutaneous venous port access, laceration repair, chest drain removal, fracture reduction)
		<i>Samples have included:</i> American, Austrian, Australian, Belgian, Brazilian, British, Canadian, Egyptian, Finnish, French, Indian, Iranian, Israeli, Italian, Korean, Swedish, Taiwanese, Thai, and Turkish children and adults	
		Has been modified for children with cognitive impairment	
CFCS	Chambers et al. (1996a)	<i>Original:</i> 13–74-month old Canadian infants and children	<i>Original:</i> post-surgical (variety of surgeries)
	Gilbert et al. (1999)		
		<i>Subsequent:</i> Age range has included: 4–14 years	<i>Subsequent contexts have included:</i> immunizations; stretching exercises; experimental pain
		Has been used in children with cerebral palsy and significant neurological impairment	
PPPM	Chambers et al. (1996b)	<i>Original:</i> 7–12-year-old Canadian children	<i>Original:</i> post-surgical (variety of surgeries)
		<i>Subsequent:</i> Age range has included 6 months–18 years	<i>Subsequent contexts have included:</i> everyday pains; post fracture reductions; chronic pain; burn injuries

(Continued)

Table 37.2 (Continued)

Measure	Primary reference	Population	Context
		<i>Samples have included:</i> American, British, Dutch, Finnish, German, Indian, and Korean children and adolescents	
PBRS	Katz et al. (1980)	<i>Original:</i> 8 month–17-year-old American children and adolescents	<i>Original:</i> bone marrow aspirations
	Revised: Katz et al. (1987)		
		<i>Subsequent:</i> Age range has included 8 months–18 years	<i>Subsequent contexts have included:</i> perioperative; various medical procedures (lumbar punctures, immunizations, venepunctures, burn injury treatment, chemotherapy, and others)
		<i>Samples have included:</i> American, Canadian, and Dutch children and adolescents	
PBCL	LeBaron and Zeltzer (1984)	<i>Original:</i> 6–17-year-old American children and adolescents	<i>Original:</i> bone marrow aspirations
		<i>Subsequent:</i> Age range has included 0.1–19 years	<i>Subsequent:</i> various medical procedures (intravenous port access, lumbar punctures, bone marrow aspirations, nasendoscopy, venepuncture, fracture reductions, laceration repairs, VCUG, paediatric assessments)
		<i>Samples have included:</i> American, Australian, Canadian, French, Greek, Italian, New Zealander, and Swedish children and adolescents	
OSBD	Original: Jay et al. (1983)	<i>Original:</i> 2–20-year-old American children and adolescents	<i>Original:</i> bone marrow aspirations
	Revised: Elliott et al. (1987)		
		<i>Subsequent:</i> Age range has included 1–18 years	<i>Subsequent:</i> perioperative; medical examinations and other examinations/procedures (bone marrow aspirations, lumbar punctures, immunizations, venepunctures, venous cannulations, dressing changes, exercise and play for children with burn injuries, fracture reduction, laceration repair)
		<i>Samples have included:</i> American, Australian, British, Italian, and New Zealander children	
CAMPIS	Blount et al. (1989)	<i>Original:</i> 5–13-year-old American children	<i>Original:</i> bone marrow aspirations and lumbar punctures
CAMPIS-R	Blount et al. (1990)		
CAMPIS-SF	Blount et al. (2001)	<i>Subsequent:</i> Age range has included 2–18 years	<i>Subsequent:</i> various medical procedures (immunizations, bone marrow aspirations, lumbar punctures, venepunctures, intramuscular injections, venous cannulations, stretching during physiotherapy, voiding cystourethrograms); cold pressor task.
		<i>Samples have included:</i> American, Australian, Canadian, British, and Portuguese children and adolescents. Modified versions have been used with Australian and Austrian samples	
			Revised versions have also been used in other laboratory analogues of child pain and/or discomfort
NCCPC	McGrath et al. (2008)	<i>Original NCCPC:</i> 3–44-year-old Canadian individuals with severe to profound cognitive impairments	<i>Original NCCPC:</i> Mixed pain episodes (every day or procedural pain)
NCCPC-Revised	Breau et al. (2002)		<i>Original NCCPC-PV:</i> postsurgical
NCCPC-Post-operative	Breau et al. (2002)	<i>Original NCPCC-PO:</i> 3–19-year-old Canadian children and adolescents with cognitive impairments	<i>Subsequent:</i> postsurgical (NCCPC); every day pains; acute pain in hospital
		<i>Subsequent:</i> Age range has included: 40 months to adult	
		<i>Samples have included:</i> French, Swiss-German, and Swedish infants, children, and adults.	

are available (Voepel-Lewis et al., 2010) and the scale has been used in many countries around the world.

### Child Facial Coding System (CFCS)

The CFCS (Chambers et al., 1996a) is a measure of children's facial movements and was categorized as an approaching well-established measure by Cohen et al. (2008). The CFCS assigns ratings to ten facial muscle movements and dichotomous scoring to three others. All 13 movements are grouped into three categories (eyes, nose, mouth). A 1 or 2 sec interval coding system is used and each facial action is coded within each interval (Gilbert et al., 1999). Scoring metrics of mean intensity and frequency (Breau et al., 2001) and total intensity (Gilbert et al., 1999) have been used. The CFCS is a high-burden measure and thus is not feasible for clinical use.

The CFCS is a modification of the well-established Facial Action Coding System (Ekman et al., 2002) and Neonatal Facial Action Coding System (Grunau and Craig, 1987). The first validation study of the CFCS examined pain in the recovery room following surgery in preschool children (Gilbert et al., 1999). Results showed good concurrent validity; CFCS scores significantly correlated with global observer visual analogue ratings of pain over various 2 min time blocks ( $r$  ranged from 0.33 to 0.73). There was also a significant negative correlation between CFCS score and time in the recovery room ( $r = -0.46$ ). Two other studies examined responsivity of the CFCS to pain. Breau et al. (2001) found a change in facial action following an immunization. Cassidy et al. (2002) found no difference in CFCS scores between distraction and standard care for children undergoing immunizations. It is unclear whether this intervention was not successful or whether the CFCS was not sensitive to this difference.

## Postoperative pain

### Parents' Postoperative Pain Measure (PPPM)

The PPPM (Chambers et al., 1996b) was developed to be completed by parents for their children at home following surgery and has been recommended for this use (von Baeyer and Spagrud, 2007). The PPPM is a 15-item dichotomous checklist designed to be easy to complete with minimal training. The majority of items ask parents to compare current to typical behaviour of the child. Example items include: whine or complain more than usual, play less than usual, hold sore part of body, and want to be close to parent more than usual. A cut-off score of 6 out of 15 has been shown to have excellent sensitivity and specificity (>80% each for day 1 and day 2 in Chambers et al., 1996b). The checklist uses an observation interval tied to daytime routines (i.e. between breakfast and lunch, lunch and supper, or supper and bedtime).

The PPPM was designed from the results of Reid et al. (1995) who asked parents for the cues they used to assess children's postoperative pain following surgery. In the original validation study (Chambers et al., 1996b) a 29-item version was reduced to 15 items using item correlations and factor analysis. Good construct validity was demonstrated through relatively high correlations with child self-report of pain ( $r = 0.61$  day 1 and 2), moderate correlations with child self-report of emotional distress ( $r = 0.39$  and  $0.27$  day 1 and 2), and decreases in scores from postoperative day 1 one to day 2. Internal consistency was also very good (Cronbach's alpha coefficients for day 1: 0.88 and day 2: 0.87) (Chambers et al., 1996b). Additional validation of the measure by Finley et al. (2003) further supported the tool's construct validity. The PPPM has also been

successfully modified for everyday pains (Francke et al., 2010) and burn injuries (Patterson et al., 2002). Ten translated versions are reportedly available (von Baeyer et al., 2011). Recently, a short-form version of the scale using the common 0 to 10 metric of pain intensity was developed by von Baeyer and colleagues (PPPM-SF; von Baeyer et al., 2011). The PPPM-SF is made up of two factors (functional interference, pain behaviours) and shows strong consistency with the original scale ( $r = 0.98$ ), high internal consistency (Cronbach's alpha = 0.85), and scores were unrelated to child sex or age. Promising construct validity of the total score was demonstrated through significantly lower scores on the second postoperative day compared to the first as well as moderate correlations with child self-report of pain intensity on both postoperative days ( $r = 0.54$  on day 1 and  $r = 0.53$  on day 2).

The FLACC (described earlier) has been identified as a well-established measure of in-hospital postoperative pain (von Baeyer and Spagrud, 2007).

## Measures of procedural distress and interactions

### Procedure Behavioral Rating Scale (also referred to as the Procedural Behavior Rating Scale; PBRS)

One of the first observational measures of child distress during painful medical procedures was the PBRS (Katz et al., 1980). The PBRS has been described as a promising assessment of distress and pain-related fear by von Baeyer and Spagrud (2007) and an approaching well-established assessment of pain and behavioural distress by Cohen et al. (2008). The PBRS originally included 13 operationally defined behaviours and was later revised to include 11 items (the two items removed were reportedly more indicative of anxiety) (Katz et al., 1987). Observers indicate the presence (or absence) of each of the behaviours for phases of the procedure (pre-procedure, procedure, recovery); scores are the sum of behaviours displayed in each phase and across all phases. The PBRS (original or revised) is relatively fast to score, but the score does not capture frequency data beyond the gross level for each phase.

The first study with the PBRS included children with cancer undergoing bone marrow aspirations (Katz et al., 1980). Interrater reliability was high across procedural phases (95% agreement; correlations ranged from  $r = 0.88$  to  $0.91$  with a grand total score correlation of  $r = 0.94$ ) and scores revealed a pattern consistent with mounting pre-procedural anxiety that peaked during the procedure and reduced somewhat during recovery. Nurses' ratings of child anxiety showed moderate to strong positive correlations with PBRS phase and total scores (ranging from  $r = 0.36$  to  $0.69$ ; Katz et al., 1982). Younger children received higher scores than older children. Subsequent research has used the original and modified versions of the PBRS to capture child distress during a variety of painful procedures including lumbar punctures (Katz et al., 1982), burn treatments (Tarnowski et al., 1987), venepunctures and immunizations (Schechter et al., 1991).

### Procedure Behavior Checklist (PBCL)

The PBCL (LeBaron and Zeltzer, 1984) was designed for use with children and adolescents undergoing bone marrow aspirations. The PBCL has been categorized as an approaching well-established assessment measure for distress and pain-related fear (von Baeyer and Spagrud, 2007), a well-established observational measure of pain and behavioural distress (Cohen et al., 2008), and has been recommended as an outcome measure of procedural distress in

paediatric pain clinical trials (McGrath et al., 2008). The PBCL includes eight operationally defined behaviours which parallel the items on the PBRs (Katz et al., 1980). Each behaviour is rated from 1 (very mild) to 5 (extremely intense) during each of three procedural phases (preprocedure, procedure, recovery) (LeBaron et al., 1984). In general, there are two forms of the scale used most commonly: the original eight-item scale (Heden et al., 2011) and a modified version including ten items (addition of groaning and flinching) (Liozzi et al., 2007). The two additional behaviours were captured and reported by LeBaron and Zeltzer (1984) in their original paper but not formally as part of the PBCL.

In the original study, interrater reliability was adequate to good (ranged from  $r = 0.64$  to  $0.86$  across the three time periods, with percent agreement ranging from 72% to 94% and overall agreement of 84%; LeBaron and Zeltzer, 1984). No sex differences emerged but younger children were more likely to score higher on the PBCL during the procedure due to an increase in demonstrative distress behaviours compared to older children. The pattern of relationships between ratings on the PBCL with observer and self-report ratings of pain indicated that the PBCL related more strongly to anxiety (versus pain) and to observer (versus self-report) ratings. For example, the relationships between the PBCL and child self-report of pain were: pre-procedure  $r = 0.26$ , procedure  $r = 0.44$ , and postprocedure  $r = -0.09$ . The parallel correlations between the PBCL and child self-reported anxiety were: pre-procedure  $r = 0.49$ , procedure  $r = 0.53$ , and post-procedure  $r = 0.21$ . Observer ratings of child anxiety were moderately to highly correlated with PBCL scores across time points ( $r$  ranged from  $0.59$  to  $0.74$ ). Observer ratings of child pain were moderately related to PBCL scores across time points ( $r$  ranged from  $0.42$  to  $0.65$ ) (LeBaron and Zeltzer 1984). Use of the PBCL to assess pain and distress behaviours has continued in a broad age range of children (Freyer et al., 1997), in a number of different medical contexts, and by researchers in a variety of countries.

### Observation Scale of Behavioral Distress (OSBD)

According to Jay et al. (1983), the OSBD is a revised version of the PBRs (Katz et al., 1980). Deemed a well-established measure by Cohen et al. (2008), the original version of OSBD contained 11 behaviours consistent with distress (pain and anxiety). A later revision of the measure eliminated three items that were infrequent or negatively related to total distress scores, leaving an eight-item scale (Elliott et al., 1987). Each behaviour is operationally-defined and the medical procedure is divided into four phases. In contrast to the PBRs procedural phases, behaviours are recorded on the OSBD as present or absent in 15 sec intervals. Each category of behaviour is also assigned an intensity weighting (e.g. screaming is weighted 4.0 whereas nervous behaviour is weighted 1.0). These intensity weightings were derived based on the average ratings provided by three health care professionals familiar with the procedure on which the measure was validated (bone marrow aspirations).

In the original study of the OSBD, interrater reliability was generally high ( $r$  ranged  $0.72$  to  $0.99$  over the phases, with the total  $r = 0.99$ ; percent agreements similarly ranged from 80% to 91% with a total agreement of 84%; Jay et al., 1983). Construct validity was supported through a variety of significant positive correlations with related constructs including children's trait anxiety ( $r = 0.63$ ), children's anticipated and experienced levels of procedural pain ( $r = 0.76$  and  $0.62$ , respectively), as well as parental ratings of child

anxiety during the clinic visit and anxiety symptoms in the preceding 24 h (both at  $r = 0.38$ ) (Jay et al., 1983). However, child state anxiety was not significantly related to OSBD scores (Jay et al., 1983). There were no reliable overall sex differences; however, similar to research with the PBRs, overall scores of the OSBD decreased with age ( $r = -0.76$ ). The OSBD and revised versions have shown sensitivity to both pharmacological and non-pharmacological pain interventions (Dahlquist et al., 1985; Jay et al., 1987). Versions of the OSBD have been used in a wide range of medical contexts including venepunctures (Dahlquist et al., 1985), dressing changes (Kanagasundaram et al., 2001), and fracture reduction (Kennedy et al., 1998).

The major limitation with the OSBD and its versions, as with several other scales of a similar nature, is the length of time required for training and coding. In addition, many studies using the OSBD have differed in their definitions and timing of phases. Some authors have pointed out that the length of phase may have little to do with child behaviour but may change the overall score of the measure (Tucker et al., 2001).

### Child Adult Medical Procedure Interaction Scale (CAMPIS)

Partially based on the OSBD (Jay et al., 1983), the CAMPIS (Blount et al., 1989) was designed to capture adult behaviour and the full spectrum of child behaviour including coping. Cohen and colleagues (2008) categorized the CAMPIS and its revisions as well established in measuring pain and behavioural distress. The original version of the CAMPIS has 35 operationally-defined verbalizations by children (16 codes) and adults (19 codes), and is administered using a continuous recording strategy. (Additional information including manuals can be accessed at: <<http://psychology.uga.edu/people/bios/faculty/BlountDoc/Blount-CAMPIS%20&%20CAMPIS-R%20no%20affect.pdf>>.) Although the CAMPIS manual includes a Likert-type scale of vocal affect coding, this has not typically been used in published studies. Overall interrater reliabilities were excellent for child and adult behaviours (kappas of  $0.92$  and  $0.80$  respectively; Blount et al., 1989).

The CAMPIS was later revised to group adult and child behaviours on empirical and conceptual bases (Blount et al., 1990). Note, however, that validation of this revision was on the same sample as the original tool (Blount et al., 1989). In the CAMPIS-R, the original 35 codes are collapsed into six categories: child distress, child coping, child neutral, adult distress promoting, adult coping promoting, and adult neutral. Continuous or interval coding can be used. In a paper exploring the validity of the CAMPIS-R, interrater reliability was good to excellent for each of the behaviour categories (e.g. child coping; kappas ranged from  $0.65$  to  $0.92$ ; Blount et al., 1992). Supporting construct validity, the code groupings showed most of the expected relationships with observational, self-report, and adult report measures of child fear and pain (Blount et al., 1997). For example, child coping was positively related to staff ratings of child cooperation ( $r = 0.37$ ) and inversely related to child distress on the OSBD ( $r = -0.49$ ) and child self-report of pain ( $r = -0.22$ ). Similarly, child distress behaviour was positively related to OSBD distress scores ( $r = 0.57$ ), child self-report of pain ( $r = 0.34$ ), and parent ratings of child pain ( $r = 0.25$ ). Adult behaviour categories showed most of the expected relationships. Parent distress promoting behaviour was related to increased child self-report of pain ( $r = 0.21$ ), OSBD distress ( $r = 0.64$ ), and inversely to staff ratings of child cooperation ( $r = -0.43$ ). Parent coping

promoting behaviours were only weakly related to staff ratings of child cooperation ( $r = 0.22$ ) and were not significantly related to child self-report of pain, fear, or OSBD distress (Blount et al., 1997). Of note, adult 'neutral' behaviours were weakly related to some outcomes. For example, parent neutral behaviours were inversely related to OSBD distress ( $r = -0.37$ ; Blount et al., 1997).

The CAMPIS-R has demonstrated sensitivity to changes in parent and/or child behaviour following intervention (Blount et al., 1992). Use of the CAMPIS and its revised version can provide exceptionally rich interactional data and description for research; these data are achieved through extensive effort however, including recording the interactions, followed by detailed post hoc transcription and coding, making the burden likely too high for clinical use.

The CAMPIS-short form (CAMPIS-SF; Blount et al., 2001) was designed to be an alternative to the CAMPIS-R that can be administered in real-time. The CAMPIS-SF removes the neutral codes and retains the child and adult distress (promoting) and coping (promoting) groups. For each phase of the procedure, behaviour groups are scored on a five-point Likert scale (e.g. 1 = none/one, 5 = maximum or nearly continuous). Initial training takes approximately 1.5 to 2 days, following which videos can be coded in real time. In the initial study, good to excellent interrater reliability was achieved (kappas ranged from 0.74 to 1.0) (Blount et al., 2001). Correlations between CAMPIS-SF child behaviours and other measures of child distress were in the expected directions (e.g. CAMPIS-SF child distress was positively correlated with OSBD distress,  $r = 0.84$ , child coping was negatively correlated with OSBD distress,  $r = -0.40$ ).

In addition to its development for lumbar punctures and bone marrow aspirations (Blount et al., 1989), the CAMPIS has been used in various forms in many procedural settings including immunizations (Blount et al., 1992; Cohen et al., 1999), venepunctures (McMurtry et al., 2010), and voiding cystourethrograms (Salmon and Pereira, 2002). The CAMPIS has also been translated into Portuguese (Pedro et al., 2010).

### Behavioural measures of pain in children with intellectual disabilities

Children with intellectual disabilities are a population for whom behavioural measurement may be particularly beneficial. Although children in this group who are higher functioning may be able to provide some degree of self-report, observation is often relied upon as a standard of measurement. A full systematic review and synthesis is beyond the scope of this chapter, but we review two scales that have been the most consistently used and demonstrate good psychometric properties with this population.

#### Non-communicating Children's Pain Checklist (NCCPC)

The most widely validated behavioural tool for assessing pain in children with intellectual disabilities is the NCCPC. The original checklist included 30 dichotomous items grouped into seven subscales and was completed by primary caregivers (McGrath, 2008). The checklist showed good internal consistency, test-retest reliability, and convergent and divergent validity (Breau et al., 2000). A revised version was published and, although the measure continues to be called a checklist, the use of ordinal ratings (zero to three) results in this new measure now being better described as a rating scale (Breau et al., 2002). The new scale (range of 0–90), still completed by primary caregivers, continued to be internally

consistent (Chronbach's  $\alpha = 0.93$ ) and showed good concurrent validity with parent-rated numerical rating scales ( $r = 0.46$ ) (Breau et al., 2002). A cut-off of 7 was found to have the best balance of sensitivity (84%) and specificity (68%). The observation time for administering the NCCPC-R is somewhat unclear. In the validation studies, caregivers reported on painful events that lasted from 1 min to 24 h and presumably provided ratings on the basis of the entire event.

A postoperative version of the NCCPC (NCCPC-Post operative; NCCPC-PO) retains the ordinal ratings of the NCCPC-R, but removes the eating/sleeping subscale (Breau et al., 2002). In an attempt to examine whether individuals other than primary caregivers could provide valid ratings using this scale, the measure was administered by both primary caregivers and research assistants. This scale further improved on the NCCPC-R by specifying an observation interval of 10 min. Similar to the NCCPC-R, the postoperative version showed good internal consistency and convergent validity (Breau et al., 2002). Excellent interrater reliability was found between caregivers and research assistants (ICC = 0.82 pre-surgery and 0.79 post-surgery), and research assistant NCCPC scores showed good convergent validity with visual analogue scale (VAS) ratings of pain ( $r = 0.72$  between NCCPC and caregiver VAS). A cut-off of 11 was deemed to be the best balance of sensitivity (88%) and specificity (81%) on the NCCPC-PO. Since its original publication, the NCCPC has been translated and validated in several other languages including French (Zabalia et al., 2011) and Swedish (Johansson et al., 2010). Further discussion of pain assessment and management in children with disabilities can be found in Chapter 16 (Belew et al., this volume).

#### Face, Legs, Activity, Cry, Consolability scale-Revised (FLACC-R)

The FLACC scale has been used in its original form and has also been revised to measure pain behaviour in children with cognitive impairment. In the first study using the FLACC with this population (Voepel-Lewis et al., 2002), nurses administered the FLACC postoperatively using an observation interval of 2 to 3 min before and after analgesic administration. FLACC scores were significantly correlated with parent global ratings of children's pain ( $r = 0.65$ ) and the FLACC was responsive to analgesic administration ( $5.3 \pm 2.8$  before analgesic,  $2.0 \pm 1.4$  after analgesic). Intraclass correlations between independent raters were significant (range 0.51–0.78), but more stringent interrater reliability analyses (exact agreement, kappa) showed some evidence of lower reliability, especially in the Legs and Activity categories (range 0.27–0.50). In a follow-up study, Malviya et al. (2006) revised the FLACC scale by adding additional behavioural descriptors within each category. Similar to the original scale, FLACC-R scores were significantly correlated with parent global ratings of children's pain ( $r = 0.74$ ). An improvement on inter-rater reliability was evident with the revised scale; intraclass correlations (range 0.75–0.90) and kappa values (0.44–0.57) were higher than those reported with the original tool.

In addition to the two scales described here, a number of other tools have been proposed to assess pain in children with cognitive impairment including the recently published Individualized Numerical Rating Scale (Solodiuk et al., 2010). Facial expression has also been suggested to evaluate pain in specific populations (e.g. children with autism; Messmer et al., 2008).

## Areas of special consideration

### Cross cultural considerations

Several of the scales reviewed have been used by researchers around the world (e.g. FLACC, CHEOPS). However, the vast majority of behavioural measures of pain have been developed and validated in English speaking populations within largely Western cultures. Although some may argue that pain behaviours should be universal, the utility of behavioural measures has recently been questioned in groups that speak languages other than English or have different cultural backgrounds (Finley et al., 2009). This argument is supported by a small body of research examining some differences in pain behaviour across infants from different cultural groups (Lewis et al., 1993; Rosmus et al., 2000). Literature on cultural considerations in behavioural measurement of pain in older children is limited. One study used the CAMPIS-R (Blount et al., 1990) to study behavioural interactions in 3- to 6-year-old Portuguese children receiving immunizations (Pedro et al., 2010). This study found that new adult behaviours were important to add in this population (e.g. intimidation, reward promise, rationalization). Literature on cultural differences in children's pain behaviour is limited, but suggests that caution be used in applying currently available measures outside of the population in which they were developed. Sweeping conclusions on the impact of culture on these measures will likely not be useful; instead, it will be important to consider individual differences in socialization and history of pain in order to best interpret pain behaviour. A detailed discussion of culture, communication and pain can be found in Chapter 11 (Clemente, this volume).

### Pain versus distress

It is important to note that not all of the behaviours included in the scales previously discussed are necessarily specific to pain. In fact, there have been questions about the utility of differentiating pain from other negative emotions especially around acute procedures (Blount and Loisel, 2009). For example, cry is a common behaviour included on many pain measures, but this same behaviour can be indicative of a range of emotions including fear, anxiety, sadness, or anger. This is particularly evident in studies of invasive procedures in which the same scale is used to measure anticipatory distress/fear/anxiety and procedural pain. There is an implied assumption that behaviours displayed before the procedure are indicative of distress and those displayed during and after the procedure are indicative of pain, but there are clear similarities in behaviours across all phases. However, distinguishing between pain and other negative emotions such as fear may be important for appropriate intervention; the ability of children, caregivers, and researchers to accurately tease apart these constructs has implications for our understanding of the pain context, accurate measurement, and targeted intervention and should be explored in future research (Bird and McMurtry, 2012).

### Modification of scales

It is clear that many scales that were developed and validated in one context have subsequently been used in other contexts. For example, the CHEOPS was originally developed for postoperative pain but has since been used in other painful procedures. In some cases, use of a measure in another context requires modification of the scale. This is particularly evident in studies using the CAMPIS

where investigators have added or removed behaviours from the measure (Caldwell-Andrews et al., 2005; Chorney et al., 2012). Although this process is not necessarily problematic, it is important that modifications are well described and further psychometric testing is completed.

## Conclusion

Although self-report is often considered the gold standard of pain measurement, authors have recently pointed out the limitations of this approach (Schiavenato and Craig, 2010). Young children and those with significant cognitive impairments may not be able to provide self-report and even in older children, self-report may not always be reliable. Contextual factors can influence children's reports of pain and may result in children over or under-reporting their experience. Measures to quantify overt behaviour are an important addition to a thorough pain assessment. Several well-validated measures are available for acute pain including procedural and postoperative contexts. One measure is available for parents as raters, but the majority of measures are designed to be administered by healthcare professionals or researchers. Some measures can be administered at the bedside, whereas others need to be administered using video recordings. There are currently two well-validated behavioural measures of pain in children with developmental delays, one of which can be administered by parents.

Although data on behavioural pain measurement are strong, a few limitations should be noted. First, most of the studies have been completed in English-speaking populations from Western cultures and the applicability of these scales outside the population in which they were originally validated is questionable. Second, although all of these scales include behaviours that have been identified by consensus and validation to be related to painful stimuli, it is important to note that none of these behaviours are specific to pain. Children may cry, grimace, or show physical tension with a range of other negative emotions.

Despite these limitations, behavioural measurement of pain is an integral part of thorough pain assessment and, in some cases, may be the most valid measure available. The availability of measures of pain behaviour and accompanying adult behaviour opens new doors to examine contextual influences on children's pain and distress. Future work in this area needs to continue to consider clinical utility and develop decision metrics around the use of these scales, particularly around decisions to treat. It is also important to acknowledge individual differences and contextual influences on pain expression and consider these in treatment decisions. Finally, given the relatively high prevalence and burden of recurrent/chronic pain in children and adolescents (King et al., 2011) further development of the understanding of the role of behavioural measurement in this area is critical.

### Case example

Molly is a 7-year-old girl who is on the medical surgical ward of a tertiary care children's hospital following an emergency appendectomy. Molly had surgery yesterday and today her nurse, Tim, has noticed that she seems to be quiet and tearful.

Molly has around the clock dosing of analgesics, but Tim suspects that she might still be having pain. Tim is aware that children in this age range can usually provide self-report of their

pain, and uses a validated tool (the Faces Pain Scale–Revised) to ask Molly to rate her pain. Molly does not talk or make eye contact with Tim when he is explaining the scale and reaches for her mother. Her mother encourages Molly to use the scale and Molly quickly points to the first face (indicating no pain). Tim and Molly's mother explain the scale again and remind Molly to point to the face that matches how she feels. Molly again points to the first face on the scale.

Outside the room, Molly's mother tells Tim that she believes Molly is having pain. She says that Molly doesn't like to take medicine and she wonders if Molly is rating her pain as very low to avoid taking medication. Tim agrees that this is possible and suggests that they use some additional ways of assessing Molly's pain. Tim knows that he will be in Molly's room for a short period of time, so wants a scale that he can administer based on a short observation. He chooses the FLACC because this scale has been validated for children in Molly's age range and in postoperative pain. Using this scale, Tim observes that Molly's face is grimaced and her jaw is clenched, her legs are tensed and restless and she is squirming in her bed, she is whimpering, but is consoled by her mother sitting in her bed with her. Using FLACC scoring, Molly scores a six out of ten. Tim takes this as additional evidence that Molly is experiencing pain. He pages the physician on call who recommends titrating Molly's medication on the basis of Tim's information. Tim discusses this plan with Molly and her mother and addresses Molly's potential concerns about taking more medication (she was worried that she would need to get another needle). He also offers to get a movie for Molly so she can be distracted. About a half hour later, Tim again assesses Molly's pain using the FLACC. Her score has decreased to one out of ten. Molly appears generally relaxed, but shifts in her bed once while Tim is observing. Tim discusses this score with Molly and her mother and Tim again asks Molly to rate her pain using the FPS–R. Molly chooses the first face of the FPS–R and Molly's mother reports that she feels Molly's pain is now well managed. Tim remind Molly and her mother to call if they feel Molly's pain is increasing again and notes that he will be back to check on them in a few hours.

## CHAPTER 38

---

# Biomarkers of pain: physiological indices of pain reactivity in infants and children

Susanne Brummelte, Tim F. Oberlander, and Kenneth D. Craig

### Summary

Biomarkers are common in all areas of clinical work, health research, and are critical indicators of diseases and physiological states. Preferably, a biomarker should be non-invasively accessible, low in cost, highly specific, sensitive, and easy to interpret. Due to the complexity of the pain system, no unidimensional reliable biomarker for pain has been identified to date. Developmental changes and delayed maturation of the involved physiological systems add another layer of complexity to the use of biomarkers in the paediatric population. Nevertheless, readily available and reliable biomarkers of pain would greatly enhance timely and appropriate treatment of pain, especially in infants and verbally or cognitively challenged children. This chapter examines currently available markers, their use, and limitations.

### Introduction

Biomarkers of health or stress reactivity are widely used in all areas of pain medicine, typically adding meaning to self-report and non-verbal measures. They are of critical importance when access to pain experience is difficult, such as in preverbal infants and in children with developmental disabilities with limited communication and social expression. The neural substrate and related endocrine, immune, and genetic components of the pain system offer a wide variety of potential biomarkers (Goldman and Koren, 2002; Oberlander and Saul, 2002). However, physiological, contextual, and developmental factors, as well as methodological factors related to the acquisition and analysis of physiological signals or biomarkers, add challenges to the use of these biological responses in infants and children. Importantly, changes in biomarker levels must be considered in the context of an infant or child's neurobiological development and environmental contexts, such as preterm

birth, neonatal intensive care unit (NICU) care, pharmacological and non-pharmacological interventions, and health and disease status (e.g. neurological injury).

No single validated unidimensional physiological marker has emerged that satisfactorily reflects painful events in children. While the expectation that a sensitive and specific marker will be discovered drives research in this field, research integrating the biological with the social-emotional nature of pain may ultimately become the most successful approach to understanding this universal but highly subjective human experience.

### Defining biomarkers and pain reactivity

Biomarkers have been defined as 'a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes or pharmacological responses to a therapeutic intervention' (Biomarkers Definitions Working Group, 2001, p. 91). Biomarkers typically can be found in everyday clinical management of health and disease; however, as the pain experience is such a subjective, multidimensional phenomenon, identification of biomarkers in this setting has been challenging (Marchi et al., 2009). To date, the focus has been on complex neurobiological system indicators that might provide reliable links between biology and pain-related experience and behaviour, such as variations in cardiac autonomic variability, immune function, brain blood flow, neuroimaging, and neuroendocrine stress hormone responses. Here, we focus on markers of particular promise, including those that have been studied sufficiently in a paediatric population. Mainly, these are measures of autonomic nervous system (ANS) function, reflected in measures of heart rate (HR) or heart rate variability (HRV), activity in the hypothalamic–pituitary–adrenal (HPA) axis (cortisol), the endogenous opioid system, in particular

beta endorphin, and genetic, inflammatory, and neuroimaging substrates with potential as biomarkers.

These physiological measures are recognized here as indices of homeostatic changes that follow a painful event. The measures seek to be specific to the nociceptive system, but invariably engage all physiological systems reactive to pain and stress, thereby typically not serving as exclusive indicators of painful responses. Access to sensitive markers of pain is of great value to clinicians, even though specificity remains an elusive objective. The properties and caveats of biomarkers need to be considered before examining in detail the multiple potential pain system markers. This perspective is offered to encourage avoidance of thinking about these indices as ‘measures of pain’.

## Setting the scene

In the first instance, having readily available and reliable non-invasive biomarkers would greatly facilitate timely recognition of pain in infants and children. While the sensitivity and specificity of a response may be questioned, physiological responses may be considered evidence of pain reactivity and should not be discounted as a ‘surrogate measure’ of pain in infants, regardless of the physiological repertoire available (Anand and Craig, 1996). The question of whether the response is specific to pain often requires clarification, with context (e.g. injury or invasive procedure) typically providing the necessary confirmation. The reactions also are important because they verify the individual’s *capacity* to mount and regulate a response in the face of a painful stimulus. ‘Pain biomarkers’ should be regarded as an index of a physiological process of ‘reactivity’ that reflects how one or more systems ‘behave’ or respond to a painful event and a capacity for recovery and not a direct measure of pain per se. These markers directly reflect features of systems that respond to stressors, and increases or decreases in the magnitude or rates of change indicate disease processes.

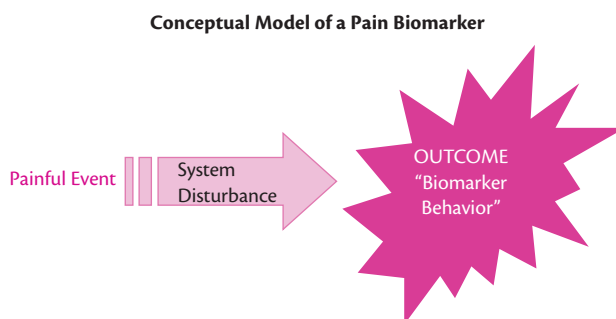

Secondly, biomarkers are used as *outcome measures* to quantify the effect of pharmacological or psychological interventions. HR, stress hormones, or catecholamine responses may be blunted by interventions, such as the use of analgesics (Anand and Hickey, 1992) or local anaesthetics (Lindh et al., 2000). Diminished reactivity presumably reflects less biological distress, thereby suggesting treatment effectiveness. However, an analgesia-induced decrease in a biomarker does not by itself indicate that pain is reduced and this needs to be verified through an association with reduced subjective distress.

Thirdly, biomarker responses are used as predictors of health and developmental outcome. For instance, higher baseline vagal or parasympathetic modulation in full-term infants predicts greater cortisol response to a heel stick at 6 months of age (Gunnar et al., 1995) and in former low birth weight infants, low biobehavioural pain reactivity at 32 weeks predicts poorer motor function at 8 months (Grunau et al., 2006). Further, more neonatal procedural pain in preterm infants in the NICU is associated with reduced white and subcortical grey matter maturation (Brummelte et al., 2012b). In this sense, features of pain exposure itself provide biomarkers that predict later development. In line with this, it is important to note that repeated exposure to painful procedures may also influence the response of a biomarker as children may transform to the repeated or continuous exposure with altered pain sensitivity (see Grunau, Chapter 4, this volume).

## Biomarker characteristics

Ideally, physiological markers would provide a meaningful biological signal with high sensitivity and specificity (Figure 38.1), such as low haemoglobin as an index of anaemia. From this perspective, a perfect biomarker for pain would be reactive to the experience and able to distinguish pain from non-noxious stressful or non-stressful events. Other desirable characteristics include availability in a fast, easy, non-invasive, and inexpensive manner and empiric validity. While HR or cortisol changes can be easily and inexpensively obtained, they are non-specific indices. Neuroimaging or genetic analysis typically are not available or even feasible and pose problems for interpretability.

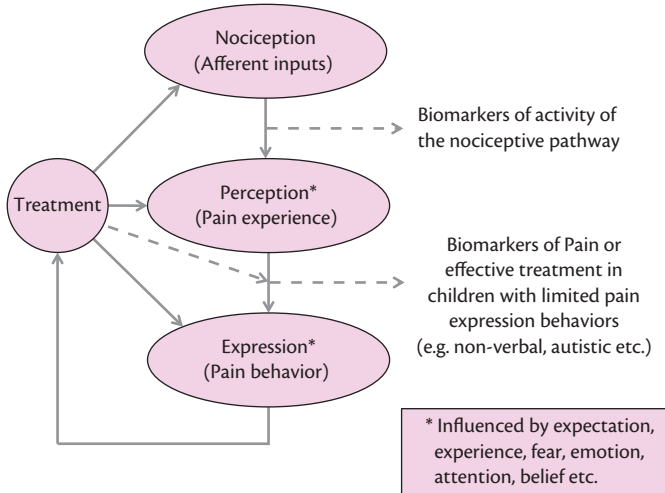

The pain system is multifaceted and typically engages a broad range of complex and interrelated biological activities that are not easily quantified. The complexity of pain experience is also reflected in self-report (Melzack, 1975) and non-verbal expression (Craig et al., 2010) measurements. The highly diverse physiological systems subserving pain include central and peripheral neural components, genes, inflammatory and endocrine markers, all of which have been studied as indices of pain reactivity (Anand and Hickey, 1987; Borsook et al., 2011a; Goldman and Koren, 2002; Peterson and Servinsky, 2007). Biomarkers reflect different levels/stages of the pain perception pathway (Figure 38.2) and it is important to understand what the index indicates for the pain experience of an individual. It may indicate features of afferent nociceptive input, but fail to account for affective and cognitive features of pain experience. Further, biomarkers considered to be related to a painful condition, may not necessarily indicate the presence of pain. For example, cystatin C can be elevated during labour pain (Mannes et al., 2003), but also during pain-controlled Caesarean sections (Eisenach et al., 2004), suggesting that this marker may disclose tissue damage rather than pain per se. Importantly, non-noxious processes such as general arousal, stress or tissue damage may all contribute to changes in potential biomarkers. In addition, markers may differ for different sources of pain, as preclinical studies suggest that inflammatory and neuropathic pain, for instance, have distinct markers (for review, see Marchi et al., 2009). Thus, pain biomarkers can be characterized as cellular, molecular, and physiological indices of processes involved in pain and pain-related generalized stress responses, but while pain is invariably stressful, not all stress is painful.

## Biomarker response patterns

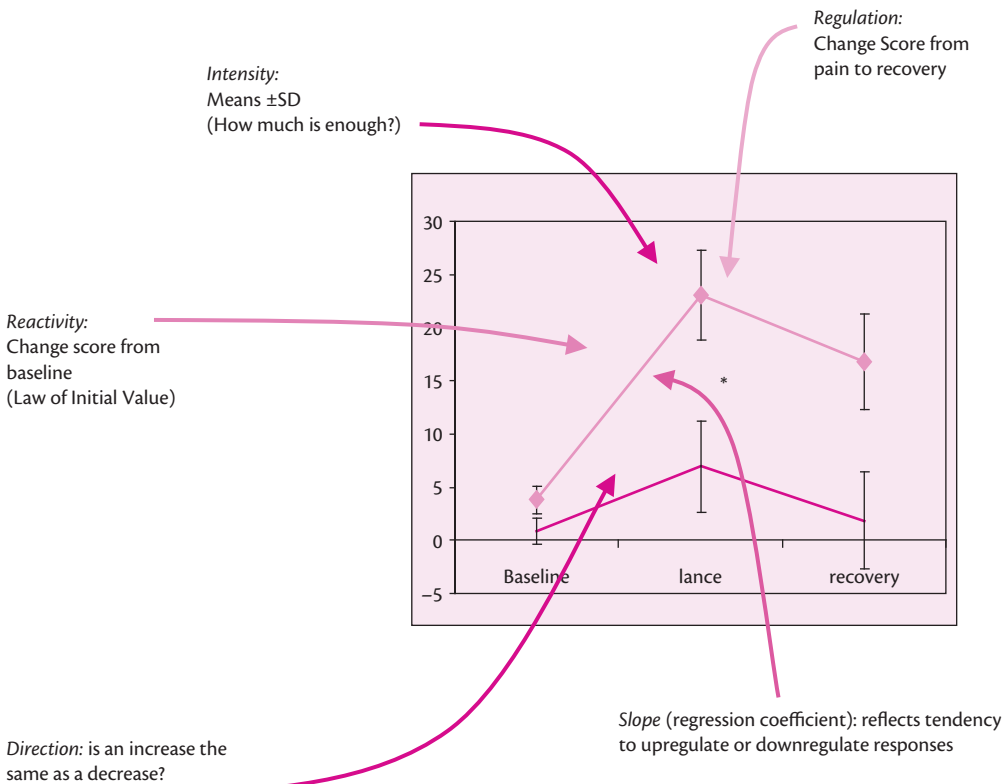

Decoding complex and variable patterns of potential biomarker activity into measurable and identifiable components is frequently challenging. The response patterns reflect processes which maintain the function of homeostatic physiological systems within a relatively narrow range. Deconstructing the complexity is typically

**Figure 38.2** Biomarkers along the pain pathway. Pathway from pain perception to pain expression in humans and potential for biomarkers of pain at each level. Adapted from Eija Kalso, Biomarkers for pain, *PAIN*, Volume 107, Issue 3, pp. 199–201, Copyright © 2004. This figure has been reproduced with permission of the International Association for the Study of Pain\* (IASP). The figure may not be reproduced for any other purpose without permission.

accomplished as follows. First, key features are identified that reflect both the amount of change from baseline, or reactivity (*intensity*), and return to baseline, the regulation phase (*recovery*) (Figure 38.3). Quantification is typically represented by a mean of multiple measures of *change scores* (simple time 1 minus time 2), along with the standard deviation. The capacity to upregulate or downregulate the response can be represented by the *slope* of the change from baseline to maximal stress or stress to recovery (Linden et al., 1997), calculated using regression coefficients. An area under the curve (AUC) measure has gained attention as a meaningful cumulative measure of reactivity and recovery, as, for instance, for the cortisol awakening response (Pruessner et al., 2003). More organized patterns of rhythmic physiological signals, such as HR, signal a greater capacity to respond to environmental demands. Rather than signalling pain, measures of changes in autonomic and central nervous system activity may reflect the neural capacity to mount a pain response and an appropriate physiological reaction to a painful stimulus.

Comparisons of responses between two or more groups require consideration of baseline levels. The Law of Initial Values asserts that the size of a psychophysiological response is dependent on the initial baseline level of the measure (Berntson et al., 1994; Wilder, 1962). Differences between groups in responses to painful events may reflect differing baselines rather than a variable impact of the noxious event itself. For example, ceiling effects have been observed; infants already in an aroused state at the onset of a noxious event may demonstrate a smaller increase in sympathetic arousal and a smaller decrease in parasympathetic withdrawal (Grunau et al., 2001).

**Figure 38.3** Quantifying components of the patterns of response to a painful event. Hypothetical reactivity patterns comparing responses in Group A vs. Group B. Patterns include measures of: *Intensity* (magnitude), *Reactivity*, *Regulation*, *Direction*, and *Slope*. Image courtesy of Tim Oberlander.

Other limits on biomarkers have been reported. A static or slow responding system or one that has a limited range of responses is less likely to provide satisfactory biomarkers than a dynamic one. Systems with inherent rhythms, such as the HPA diurnal pattern, may bias against observing an acute response to a painful event if one samples during a morning cortisol peak period. A predictable response pattern is easier to observe when the signal returns to a baseline compared with a response pattern that remains elevated (continuous response) or has an unpredictable or paroxysmal pattern following a stressful event (see Figure 38.4). Thus, consideration must be given to a biomarker's typical response pattern and contextual influences to appreciate its behaviour in a painful context.

## Heart rate and heart rate variability

The ANS plays a key part in the homeostatic response to internal demands and external challenges (stress). Thus, measures of ANS function such as HR or HRV are well suited as biomarkers as these are biological signals that reflect components of the stress and/or pain response systems. HRV reflects variation in the time between heart beats and is a natural occurring physiological phenomenon. ANS function can be easily studied via non-invasive methods and displays a fast (within seconds) response and recovery pattern that can be quantified to yield measures of magnitude, variability, and direction of the signal (see Figures 38.3 and 38.4). Effects are mediated via two branches, parasympathetic and sympathetic, and responses can be quantified to yield discrete continuous and bi-directional indexes of relationships between both branches (Berntson et al., 1997; Grossman, 1992).

HR, particularly variations linked to respiratory patterns (vagal tone), provides commonly used autonomic biomarkers (Porges, 1992). Systems that control autonomic aspects of cardiovascular

function are closely linked to systems that modulate pain reactivity (Randich and Maixner, 1984) and activation of vagal afferents can both facilitate and inhibit nociception (Lovick, 1993).

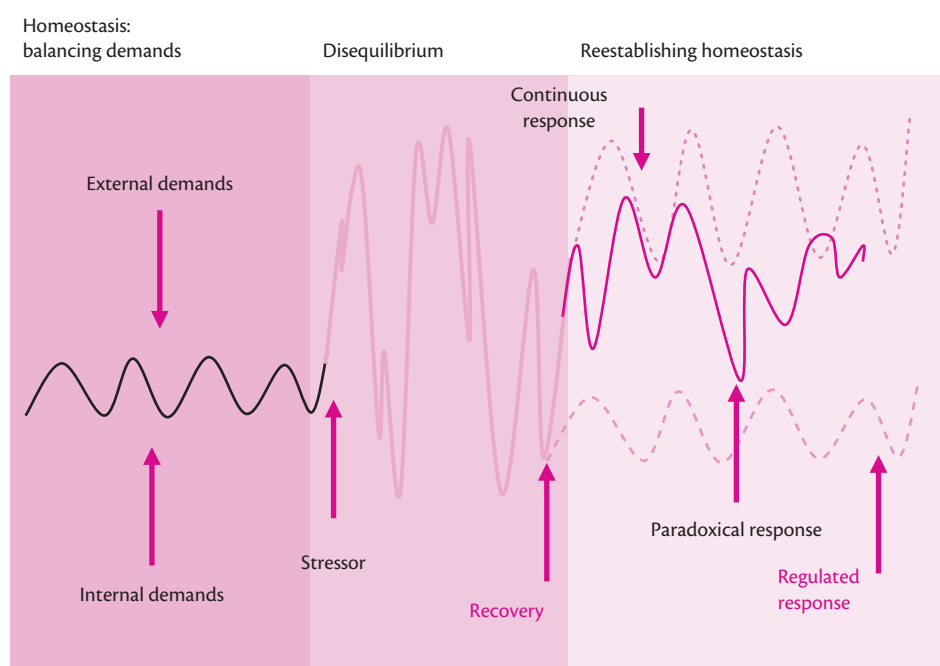

Developmental maturation of the ANS has to be taken into account when investigating HR and HRV. Typically, mean basilar HR among term-born infants increases to a maximum in the first 2 months of life and then decreases through infancy (Doussard-Roosevelt et al., 1997). In contrast, HRV undergoes opposite changes, and after the first 2 months of life is generally positively correlated with age (Finley and Nugent, 1995; Massin and von Bernuth, 1997). HR typically shows an immediate increase following the noxious event (Craig et al., 1993; Oberlander and Saul, 2002) and a decline during recovery. However, in infants a short decrease in HR has been described 3 to 5 sec after a vaccine, followed by the characteristic increase (Johnston and Strada, 1986).

Further, critical measurement and contextual caveats need to be considered in using HRV measures. HRV varies with the length of the HR epoch assessed and proximity to the noxious event. HRV increases as the length of the record increases (McIntosh et al., 1993; Oberlander et al., 2000; Saul et al., 1988). See Voss et al. (2009) for a review of methodological considerations in the use of HRV.

## Cortisol measures

Cortisol is the predominant glucocorticoid in humans and it regulates homeostatic stress responses by mobilizing energy to meet the body's needs, such as elevating blood glucose levels. In response to a stressor, the HPA axis releases cortisol from the adrenal cortex, thus offering a key stress biomarker reflecting both central and peripheral reactivity.

Salivary cortisol can be non-invasively obtained and has been more widely studied as a biomarker of affective and behavioural responses to stress than pain per se (for review, see Dickerson

**Figure 38.4** Phases and patterns of biomarker reactivity. Hypothetical characteristic behaviours of a stress/pain biomarkers extending from an undisturbed baseline condition to acute response phase (reactivity) to recovery (regulation of response) period. Image courtesy of Tim Oberlander.

and Kemeny, 2004; Hellhammer et al., 2009). Importantly, cortisol increases take minutes before they can be observed in saliva or blood, thus cortisol is a rather slow or 'long-acting' component of stress reactivity.

The cortisol awakening response has been associated with experimental pain ratings in adults (e.g. Goodin et al., 2012). Pain or stressful events reliably elicit a cortisol increase in men and women aged 18 or older; however, in children or adolescents, stressful situations or painful experiences such as inoculations or blood draws do not always lead to significant increases in cortisol levels (for review, see Gunnar et al., 2009). It has been suggested that pain- or stress-induced HPA axis activation in children may vary with the social environment, such as comforting or distracting parental behaviour (McCarthy et al., 2011), demonstrating central regulation of the HPA axis and thus explaining diminished or absent increases in cortisol in certain situations (Gunnar et al., 2009). Thus, cortisol may not be a reliable diagnostic marker for pain experience in a paediatric population.

However, cortisol patterns associated with pain exposure early in life may serve as a biomarker for predicting subsequent HPA axis stress function. Greater cumulative neonatal pain exposure in preterm infants was associated with higher basal cortisol levels during a visual novelty task at 8 months of age (Grunau et al., 2004) and early pain exposure, even when controlling for morphine exposure, predicts cortisol levels up to school age in children born preterm (Brummelte et al., 2012a). These studies suggest that exposure to multiple painful events during the preterm period may contribute to 'resetting' subsequent basal arousal systems, which may regulate the HPA axis system. There is increasing recognition that early experience at critical time periods, perhaps manifesting itself through epigenetic effects and brain neuroplasticity, can change neurocognitive development (Meaney, 2010; Neville and Bavelier, 2002).

## Endogenous opioids as markers of pain

Endogenous opioids are an important component of the anti-nociceptive system (Millan, 2002). Plasma beta endorphin (BE) levels are easy to obtain and are often examined as they relate to acute and chronic pain outcomes (Bruehl et al., 2012). It has been suggested that elevated resting plasma BE levels may be a potential biomarker for reduced endogenous opioid analgesic capacity (Bruehl et al., 2012). BE produces analgesia by binding to opioid receptors (particularly of the mu subtype) at both pre- and postsynaptic nerve terminals in the peripheral nervous system. Through a cascade of interactions, binding of BE results in inhibition of the release of tachykinins, particularly substance P, a key protein involved in the transmission of pain (Stein, 1995). In adults, it has been shown that the degree of pain experienced by a surgical patient during and after a procedure correlates with plasma BE levels (Sprouse-Blum et al., 2010). Further, both pre- and postoperative plasma BE levels correlate positively with postoperative pain severity for various major surgeries (Matejec et al., 2003). Thus, BE levels can be elevated in response to increased pain, probably as a result of increased endogenous analgesia, but increases have also been found in response to exogenous analgesia (El-Sheikh and Boswell, 2004), which makes the interpretation of this signal challenging.

In neonates, infants and children, BE levels did not increase significantly after (pain-controlled) surgery (Mirilas et al., 2010),

although levels were greater preoperatively compared to non-surgical patients in neonates and school-age children. This lack of increase has been interpreted as a protection from surgical stress and postoperative pain by fentanyl/propofol anaesthesia (Mirilas et al., 2010). Further, one study found significantly lower BE levels in juvenile patients suffering from migraines or headaches compared to healthy controls (Battistella et al., 1996), while another study found significantly increased levels in a group of children suffering from a painful atopic dermatitis (pruritus) compared to controls or children with healed (non-painful) dermatitis (Georgala et al., 1994). Similarly, positive and negative associations between pain ratings and BE concentrations in children undergoing painful procedures have been reported (Bachiooco et al., 1995; Katz et al., 1982). More studies are needed to better understand the BE response to acute and chronic pain in children.

## Other biomarkers: skin conductance

In response to pain, as well as other sources of stress, skin sympathetic nerves release acetylcholine, which acts on muscarine receptors leading to increases in skin conductance. Changes in skin conductance react immediately and are described as continuous, objective, and more sensitive and specific than other currently available biomarkers for assessing pain (Storm, 2008). They have been reported to have a high sensitivity to pain (about 90%) and moderately high specificity (about 60%) in both children and adults (Hullett et al., 2009; Ledowski et al., 2007), at least for moderate to severe pain (Breimhorst et al., 2011; Loggia et al., 2011b; Munsters et al., 2012; Pereira-da-Silva et al., 2012). Studies have demonstrated associations between self-reported pain and skin conductance fluctuations in postoperative paediatric patients aged 1 to 16 years (Hullett et al., 2009), as well as poor correlation of skin conductance with self-reported pain scores (Choo et al., 2010).

Recent studies have raised concern about the reliability (Breimhorst et al., 2011) and specificity of electrodermal activity. For instance, central sympathetic inhibitory drugs and sympathetic nerve activation like nausea, vomiting, and anxiety may influence the skin conductance index (Storm, 2008). Importantly, abundant tactile stimulation and high-sound levels in the neonatal units yield stress responses similar to heel stick when monitored using plasma catecholamine and skin conductance (Bremner and Fitzgerald, 2008; Hellerud and Storm, 2002; Lagercrantz et al., 1986), questioning its specificity. In addition, a recent study by Valkenburg et al. (2012) demonstrated that skin conductance peaks could result from changes in vital parameters such as skin temperature and may thus be unrelated to pain. Skin conductance may provide an additional easy to use and non-invasive tool, but more research is needed to confirm its specificity and to determine the clinical applicability of the method.

## Inflammatory and genetic markers

Inflammatory markers have been associated with pain. However, most of these cytokines are not specific to pain, but are released in response to inflammation or tissue damage. Nevertheless, altered cytokine levels have been associated with chronic pain. For instance, Slade et al. (2011) identified monocyte chemoattractant peptide (MCP)-1, interleukin (IL)-1 $\alpha$ , IL-8, and transforming growth factor (TGF) $\beta$ 1 as potential diagnostic markers and therapeutic

targets for pain in patients with temporomandibular disorder. Animal models suggest that alterations in specific cytokine levels and their receptors contribute to the development and maintenance of chronic pain (e.g. Abbadie et al., 2009). Therefore, these markers may represent novel targets for therapeutic intervention. More research is needed to confirm this association and its specificity for pain, especially in children.

Recent research on genetic variability and the association of certain genotypes with altered drug metabolism underlines the importance of taking genetic variants into account when analysing or interpreting biomarkers. Evidence is evolving demonstrating the increased risk of certain genotypes for developing chronic pain. For instance, Diatchenko and colleagues (2005) demonstrated that variants of the gene encoding catecholamine-O-methyltransferase (COMT), an enzyme that controls levels of adrenaline and other chemicals and is released in response to stress, influenced both human pain perception and sensitivity and the risk for developing a chronic pain condition. Intriguingly, the COMT genotype was a stronger predictor of overall pain severity than burn size, burn depth, or time from admission to pain interview assessment in individuals hospitalized after thermal burn injury (Orrey et al., 2012). A case-control study of children suffering from chronic tension-type headache (CTTH) investigating the Val158Met polymorphism of the COMT gene found that children expressing the Met/Met genotype showed a longer headache history and lower pressure pain thresholds compared with those with Met/Val or Val/Val genotype, but no increased predisposition to suffer from CTTH in children (Fernandez-de-las-Penas et al., 2011). Studies have demonstrated altered ANS activity (e.g. heart rate changes) and cortisol levels in children in response to stressors depending on the COMT or serotonin transporter genotype (Armbruster et al., 2011; Mueller et al., 2011). Gene-environment interactions have been investigated (e.g. Mueller et al., 2011), with recent studies in adults suggesting that the Val158Met polymorphism contributes to interindividual differences in neural pain-processing by affecting cognitive aspects of pain processing (Loggia et al., 2011a; Schmahl et al., 2012). However, further research with children is needed on this topic. More genetic variants have been identified in recent years (e.g. in the gene encoding the P2X7 receptor; Sorge et al., 2012) or the endothelin-receptor A (EDNRA; Kleiber et al., 2007), but their potential as markers of pain and as novel targets for therapeutics, particularly in the paediatric population, remains unknown. These studies broaden our understanding of individual differences in pain sensitivities and may help to identify children at risk for developing chronic pain.

## Neuroimaging as a biomarker

Neuroimaging applications allow the study of human brain function *in vivo*. Techniques have been developed which offer different temporal, spatial, or spectral resolutions. These methods have identified which brain areas are activated during a painful procedure in the adult human brain and indicate that touch and pain display uniquely different evoked potentials (Apkarian et al., 2011). The major challenge for using neuroimaging as a marker of pain or pain intensity is that most of the available techniques, such as electroencephalography (EEG), advanced magnetic imaging, or magnetoencephalography (MEG), require complex instrumentation that is very costly and not easily accessible for everyday

clinical procedures. These methods have been valuable however in understanding long-term changes and neural plasticity in response to acute and chronic pain in the developing brain. As functional imaging offers a non-invasive 'window' into the developing brain, these applications provide promising tools to assess the nature of the pain experience in infants and in children with chronic pain and to provide insights into potential treatments for pain (Borsook et al., 2011b; Holsti et al., 2011; Ranger et al., 2011; Sava et al., 2009). However, not unlike the concern with other biomarkers of pain, the specificity of the marker, i.e. the specificity of the cognitive activation map in response to pain is still an issue, as there is again overlap with other physiological systems such as arousal or stress.

## Biomarkers in special populations

### Premature care and early infancy

Contextual variables inherent to the painful event have important implications for selection and use of biomarkers (Sellam et al., 2011). In a NICU setting, greater exposure to painful procedures, sex, and ventilation have been associated with physiological response to heel sticks (Sellam et al., 2013). Health status of the infant demonstrably alters the 'performance' of biomarkers (Goldstein et al., 1998). Similarly, mechanical ventilation, reduced lung compliance, neurological compromise from birth asphyxia, intraventricular haemorrhage, or periventricular leucomalacia have all been associated with altered HRV and parasympathetic function (Hanna et al., 2000; Prietsch et al., 1994; van Ravenswaaij-Arts et al., 1995).

Not surprisingly, opioid analgesia may influence a biomarker's response to a painful stimulus. In preterm and term infants, opioids reduce HR responses to noxious events. In neonates, opioids decrease cardiovascular responses to surgical stress (Anand and Hickey, 1992). However, response to opioid analgesics varies with the basal state of the infant. When not in pain, opioids produce tachycardia and increased ventricular contractility by way of reflex sympathetic activation. These adverse side effects can be prevented by beta-adrenergic blockade (Franz et al., 1982; Vatner et al., 1975). In contrast, under conditions of high initial sympathetic activity such as pain or stress, opioids decrease blood pressure by a centrally mediated sympatholysis (Lowenstein et al., 1969). These differing, contrary and context-based opioid-mediated effects make it essential to account for these factors when interpreting an infant's clinical pain response. Interestingly, even simple procedures such as routine tactile nursing procedures can modulate HR and behavioural reactivity to pain in very preterm infants if they are preformed shortly before a painful procedure, suggesting that a heightened state of arousal affected modulation of HR in response to pain (Holsti et al., 2006). Further, a recent study by Slater et al. (2012) showed that preterm infants undergoing a tissue-damaging procedure had higher concentrations of uric acid and malondialdehyde in plasma compared to infants not experiencing any tissue damage, indicating elevated oxidative stress. Malondialdehyde levels were also significantly correlated with pain scores measured with the Premature Infant Pain Profile, suggesting a relationship between procedural pain and oxidative stress in preterm infants. Such an association may prove helpful to determine preterm infants' pain levels in the future, but more research is needed on this topic.

Among preterm infants, sympathetic control appears to dominate, while parasympathetic influences become predominant near term and beyond. Thus, in preterm infants, HRV increases with age

but remains lower at term compared with term-born infants, suggesting continued maturational delay (Porges, 1992). Importantly, small for gestational age infants may have a higher HR and lower HRV when compared with appropriate for gestational age term-born infants (Spassov et al., 1994), suggesting that trends in maturation of cardiac autonomic control may be related to both gestational age and level of neurological maturity. Similarly, the HPA axis is still immature in preterm infants and cortisol levels are often inappropriately low in infants in the NICU (Fernandez et al., 2008; Hanna et al., 1993; Kari et al., 1996). Further, it is challenging to obtain blood or sufficient saliva from these infants to measure cortisol in a timely pattern.

Conceptual age and early pain experience are also important modifiers. Preterm infants (<28 weeks) have been shown to be more responsive to procedures as they progress towards term (i.e. their HR responses become increasingly more vigorous) (Porter et al., 1999). Maximum HR response to a heel lance in infants born at 28 weeks, but studied at 4 weeks of extrauterine life, was higher when compared with infants born at 32 weeks' gestational age (Johnston et al., 1996). Differences in HR, HRV, and cortisol at various ages may be due to the early adverse experiences such as repeated pain exposure (Grunau et al., 2005) and may reflect a permanent reprogramming of the ANS or HPA axis, which needs to be taken into consideration when trying to interpret a biomarker's level or response.

### Pain biomarkers in the context of developmental disabilities

Children with profound intellectual or developmental disabilities are often non-verbal or otherwise communicatively impaired which makes it difficult to reliably assess pain status through conventional means (i.e. self-report). In these cases, facial action coding has been used to successfully identify painful experiences during invasive procedures (Grunau et al., 1990; LaChapelle et al., 1999; Nader et al., 2004; Oberlander et al., 1999). Some studies indicate that prior reports of reduced pain sensitivity in these populations arose from failure to use appropriate assessment procedures rather than insensitivity in these populations (Tordjman et al., 2009). For instance, it was believed that sensory processing is reduced and pain is absent or blunted among individuals with intellectual and related neurodevelopmental disorders (IDDs) and chronic self-injurious behaviour (SIB), but new data suggests higher (not lower) levels of reactivity to an array of calibrated sensory stimuli for individuals with chronic SIB (Symons, 2011). Similarly, Tordjman et al. (2009) reported greater heart rate response to venepuncture and the elevated plasma beta-endorphin levels in individuals with autism, which reflects enhanced physiological and biological stress responses. This is consistent with the findings of Nader et al. (2004) demonstrating more vigorous facial displays during venepuncture in children with autism. These results indicate that children with autism are sensitive to pain, despite prior reports of reduced pain sensitivity (Tordjman et al., 2009). These studies underline the need for reliable physiological biomarkers of pain, which can be used in addition to conventional measures and behavioural observations. Children with cognitive or emotional impairments may have different modes of expressing their pain, and having physiological indices of nociception or pain perception available would be a tremendous asset to help reduce the suffering of these patients.

## Conclusion

While multiple biomarkers are readily available for use in studies of pain reactivity, no single biomarker characterizes all aspects of paediatric pain. Pain system function early in life has complex interrelationships with other developmentally sensitive stress reactivity systems and drawing a single conclusion about 'pain biomarker responses' based on the observation of function of one system is questionable. Typical childhood contexts vary and influence a marker to 'behave' differently under different contextual and illness conditions.

From an evolutionary point of view, behavioural responses such as facial expression and crying are still the best indicators of pain, as mothers did not, and still do not, carry around heart rate monitors or EEG equipment. Modern techniques help us to better understand pain perception and consequences of chronic pain in a population-based model, but are often not reliable in predicting individual responses or outcomes. In contrast, genetic variations such as the COMT or hepatic metabolic factors may prove to be valuable predictors of pain sensitivity in adults and hold future promise for individualized anaesthesia models and pain treatments.

It is important to recognize that while pain may be a universal human experience it is by nature a complex and variable phenomenon (Melzack, 1975), both within individuals, over time, and across populations. Understanding the pain of another person requires considerable careful judgement, including the need to integrate various sources of information, such as self-report, non-verbal expression and evidence of injury or disease. While all experience has biological substrates, the challenge of identifying and measuring biomarkers for such a diverse experience as pain is significant, as many factors, such as the cost, non-invasive accessibility, dependence on environmental factors, the specificity, sensitivity, and speed of the response pattern, as well as developmental changes and/or delayed maturation of the involved physiological systems need to be considered.

Taken together, we are in urgent need of 'better' physiological biomarkers of pain to reliably assess pain in non-verbal or otherwise challenged children that would work towards identifying the best multidimensional approach to understand and effectively treat pain in the paediatric patients.

### Case example: irritability of unknown origin—making sense of biomarker pain signals?

George is a 12-year-old with multiple developmental disabilities associated with a significant neurological impairment of an unknown genetic-metabolic disorder. He has multiple cognitive, language, and motor impairments, is fed via a gastrostomy tube, has infrequent seizures, and has been treated for gastro-oesophageal reflux. He has a ventriculoperitoneal shunt for hydrocephalus and is thought to have recurrent headaches—there is a family history of migraines.

George's medications include valproic acid, ranitidine, and lactulose, with glycerine suppositories, phosphate enemas, acetaminophen, and lorazepam, as needed. His parents and caregivers rely on a variety of non-specific verbal and hand and head movements to understand his communication of pleasure or discomfort. Increasingly, he engages in SIB. His symptoms have increased in frequency, duration, and intensity and

particularly troubling are his continuous facial grimacing. In the rare moments when he is not crying his parents report that he becomes irritable and typical sensory experiences that had been pleasant were now ineffective or even aversive. One night, George awoke crying with increased vigour. Finding that he had no fever, but his HR was 150/min at rest and he was breathing rapidly (>40/min), his father stopped an overnight feed. Because of increased generalized arousal and irritability, which his mother thinks reflects a severe painful condition, he was brought to his local emergency department.

On examination he was agitated and engaged in SIB (hitting his left ear) coupled with a grimace. He was afebrile but responsive to touch and his heart rate was 80/min and regular, and respiratory rate was 15/min. Laboratory investigations revealed a white blood count of 18 000, with a left shift and erythrocyte sedimentation rate of 45. Chest X-ray was typical and consistent with previous images. The residents who examined him were puzzled—he appeared to all as if he might be in pain, but his cardiorespiratory status was telling a different story—where were the ‘pain signals’, they asked?

## CHAPTER 39

# The neurophysiological evaluation of nociceptive responses in neonates

Ravi Poorun and Rebecca Slater

### Summary

Human pain and suffering is most often communicated by language. The ability to communicate verbally puts adults and older children at a distinct advantage over our young counterparts. Infants and newborns cannot talk—which makes the reliable subjective measurement of pain difficult in this population. In neonates, we have traditionally relied on objective measurements of physiological and behavioural responses to noxious stimulation (Stevens et al., 2007), and research continues to search for the best measures of pain in neonates (Stevens and Franck, 2001; see also Lee and Stevens, Chapter 35, this volume).

In this chapter we review the use of quantitative neurophysiological techniques to evaluate nociceptive responses in the central nervous system of the neonate. We will discuss how:

- ♦ electromyography (EMG) can be used to measure flexion reflex withdrawal.
- ♦ near-infrared spectroscopy (NIRS) and electroencephalography (EEG) can be used to measure brain activity evoked by noxious stimulation.
- ♦ magnetic resonance imaging (MRI) may be exploited to investigate the development of nociceptive processing in the neonatal and infant brain.

The appropriate use of these techniques may help us understand how the functional development of the human brain enables processing of nociceptive stimuli.

### Introduction

It was once a long-held belief that due to the immaturity of the peripheral and central nervous systems, neonates did not feel pain. Coupled with limited data regarding the safety and efficacy of analgesia in neonates, minimal analgesia was often administered for procedures that would most certainly be painful in adults (Anand et al., 1987). Over the past 30 years, the study of childhood and infant pain has evolved to become a subject of active research (McGrath and Unruh, 2002). It is now accepted that human infants

process noxious stimuli, and that this information is transmitted to the brain. However, while the use of neurophysiological and neuroimaging techniques has been extensively used in the study of adult pain, these techniques have had relatively limited use in evaluating the response to nociceptive stimuli in neonates and infants. Neurophysiological measures in older children are discussed by Hermann (Chapter 40, this volume).

Key stages of anatomical development have been identified in the human infant brain, such as:

- ♦ The growth of thalamocortical axons into the cortical plate from 26 gestational weeks (Kostovic and Judas, 2002).
- ♦ The elaboration of terminals and onset of cortical differentiation from 31 weeks.
- ♦ The formation of callosal and association pathways from 34 weeks (Kostovic and Judas, 2010).

However, almost nothing is known about the functional correlates of these events. Through investigation of the developing human nervous system we can try to ask ‘What is the pattern of brain activity that underpins the human experience of pain?’. In the adult brain, numerous structures are involved in the experience of pain, including the brainstem, thalamus, and a rich variety of cortical areas, which includes the somatosensory cortex, cingulate cortex, insula, and amygdale (Tracey and Mantyh, 2007). However, the extent to which these structures are involved in infant pain is unknown. Direct measurement of brain activity, using a variety of techniques, will further our understanding of how noxious events are processed by the infant nervous system. In this chapter we will highlight some of the important advances that have been made using neurophysiological measures to study responses to noxious and non-noxious stimuli in early life.

### Electromyography

Electromyography (EMG) records the electrical activity produced by skeletal muscle. In neonates, surface EMG is preferred over the more-invasive intramuscular EMG techniques, and is most often used to monitor the flexion reflex withdrawal activity of the

underlying biceps femoris in the posterior thigh, or tibialis anterior in the anterolateral lower leg. The flexion withdrawal reflex (Sherrington, 1910) has been used in adult subjects to study the spinal processing of nociceptive stimuli (Willer, 1977) and analgesic sensitivity (Willer, 1985). In both preterm and term neonates, the flexion reflex can be evoked by mechanical or electrical stimulation (Andrews and Fitzgerald, 1994, 1997, 1999; Fitzgerald et al., 1989). However, the stimulus intensity or threshold for eliciting reflex activity is lower than in adults (Hugon, 1973), and reflexes can be elicited by non-painful stimuli. Increasing age sees a gradual reorganization and decrease in spinal cord excitability (Jennings and Fitzgerald, 1996, 1998; see also Walker and Baccei, Chapter 6, this volume), which is accompanied by a rise in threshold of the neonatal withdrawal reflex (Andrews and Fitzgerald, 1994; Fitzgerald et al., 1988). Below 35 weeks postconceptual age, preterm infants display sensitization to innocuous stimuli and a reduction in threshold (Andrews and Fitzgerald, 1994) whilst older infants display habituation to the same non-noxious stimuli. Habituation is characterized by a reduction in the number of observed reflex withdrawal responses but with no alteration in withdrawal threshold following repeated stimulation (Andrews and Fitzgerald, 1994; Fitzgerald et al., 1988). Similarly, habituation of reflex responses can be seen in adults with intact or divided spinal cords (Dimitrijević and Nathan, 1970; Dimitrijević et al., 1972).

Over the postnatal period, somatosensory and motor pathways in the central nervous system (CNS) are continually maturing (Fitzgerald, 2005). While EMG techniques cannot tell us anything about the subjective experience or perception of pain, they are extremely useful in understanding the development of spinal nociceptive processing.

## Near-infrared spectroscopy

Near-infrared spectroscopy (NIRS) can be used to measure blood and tissue oxygenation. The method is based on spectroscopic measurements of oxygenated and deoxygenated haemoglobin concentration and depends on the transparency of biological tissue to near-infrared light. It uses the optical property that the absorption of near-infrared light is dependent on the amount of oxygenated and deoxygenated haemoglobin present in the tissue (Owen-Reece et al., 1999). Source and detector pairs can be placed on the surface of the skull and local changes in the intensity of the emitted and absorbed light can quantify changes in tissue oxygenation. In addition, absolute parameters such as blood flow and cerebral blood volume can be calculated. The measurement of changes in haemodynamic activity—as a proxy measure of functional brain activity—is based on the assumption that increased tissue oxygenation represents an increase in regional cerebral blood flow, associated with an increase in underlying neural activity (Logothetis et al., 2001).

NIRS is widely used in neonatal research to measure functional activation of the cortex (Kusaka et al., 2004). Recently, this technique has been used in neonatal studies investigating cerebral responses following noxious stimulation. Cortical haemodynamic activity has been recorded in infants in response to noxious events, including heel lance, venepuncture, and endotracheal tube suctioning and repositioning (Bartocci et al., 2006; Limperopoulos et al., 2008; Slater et al., 2006, 2008). These studies suggest that an increase in haemoglobin concentration can be observed in the

somatosensory cortex in preterm neonates from approximately 25 weeks of gestation. The magnitude of this activity is dependent on the infant's age, but is also influenced by other clinical features, such as the sleep state of the infants. Similar changes in haemoglobin concentration in the somatosensory cortex were not found when non-skin-breaking tactile stimuli were applied to the surface of the skin, even though reflex withdrawal responses were observed, suggesting the observed changes in brain activity were related to the noxious input.

Using NIRS for clinical bedside pain assessment remains challenging because movement artefacts can interfere with the quality of the recorded signal and there is an extremely high attrition rate for recording of high-quality data. However, with secure optode placement, movement artefacts can be minimized, and careful control of the infants' environment can improve the quality and accuracy of the recordings. Further NIRS studies have demonstrated that following noxious stimuli there is a good correlation between the magnitude of the haemodynamic changes recorded in the contralateral somatosensory cortex and the more classically recorded change in neonatal facial expression (Slater et al., 2009). Other experimental and clinical conditions have also been shown to alter the size of the haemodynamic response, such as the location of the stimulus and the number of prior painful procedures (Ozawa et al., 2010, 2011; Slater et al., 2006). Importantly, all these studies lead to the conclusion that infants who are exposed to noxious stimuli during this immature developmental period, process this information at the level of the cortex, even though some infants do not manifest an observable behavioural response (Slater et al., 2008).

These studies provide some evidence that preterm and newborn infant responses to noxious stimulation are not purely reflexive, but the information is transmitted to the infant cortex. While this does not provide evidence of the perception of pain and cannot tell us what an infant feels, it is likely that activity in higher-level cortical regions of the brain is necessary, though maybe not sufficient, for the perception of pain.

## Electroencephalography and evoked potentials

Electroencephalography (EEG) has been extensively used to investigate neurological function in neonates and infants. The technique provides an opportunity to record the electrical activity generated by large populations of cerebral neurons. An EEG represents fluctuating electrical field potentials as a function of time, and the deflections represent changes in voltage and polarity. By recording from multiple electrode sites, it is possible to obtain a representation of the spatial distribution of the electric field recorded over the scalp. EEG is often characterized by the frequency and amplitude of the recorded activity and during the early neonatal period the characteristic patterns of EEG activity change rapidly with gestational age (André et al., 2010). For example, throughout early developmental there is a reduction in the discontinuity observed in the EEG recordings. In addition, an increase in characterized rhythmical patterns of activity, such as delta brushes and temporal sawtooth waveforms, is observed, followed by their subsequent disappearance (Dreyfus-Brisac and Monod, 1972). The identification of these characteristic patterns of EEG activity during this developmental period is often used in the clinical assessment of neonatal cerebral function.

EEG can be used to measure specific patterns of brain activity recorded in response to known stimuli. These evoked patterns of activity are referred to as evoked or event-related potentials. In neonatal pain research, specific changes in EEG activity have been recorded in response to acute noxious stimulation, such as a clinically essential heel lance (Slater et al., 2010a, 2010b). By considering the features of the evoked activity, such as the polarity, timing, and topography, inference can be made about the how the brain processes noxious sensory information.

An event-locking technique has been developed to enable the evoked neuronal activity following a single clinical noxious event to be recorded (Fabrizi et al., 2011; Worley et al., 2012). Use of this technique has provided electrophysiological evidence that the immature infant brain can discriminate between acute noxious and non-noxious stimulation from 35 gestational weeks (Slater et al., 2010a). These electrophysiological measures of nociceptive-specific brain activity are useful for understanding how the developing human brain responds to nociceptive stimuli, and may potentially be useful to test the ability of analgesic treatments in neonates to suppress these increases in brain activity. Nevertheless, these experimental studies are challenging and require specialist data acquisition and analysis skills (Fabrizi et al., 2011; Vanhatalo et al., 2009; Worley et al., 2012).

Investigation of the maturation of EEG responses to peripheral stimuli in infants from 28 weeks of gestation has shown that these evoked patterns of activity only become dominant after approximately 35 weeks of gestation (Fabrizi et al., 2011). There appears to be a gradual shift with advancing maturity, from non-specific bursts of neuronal activity to modality-specific activity that is discriminative between noxious and non-noxious events. A further study that has investigated clinical factors that modulate this activity demonstrates that infants born preterm (24–32 weeks of gestation) who have reached their due date have a larger evoked response following noxious stimulation than normal term-born infants (Slater et al., 2010b). In contrast, there is no difference in the magnitude of the evoked response following non-noxious stimulation. Although it cannot be concluded that prior pain experience specifically alters the subsequent processing of nociceptive information, it is clear that some aspect of being born preterm differentially alters the cerebral response to nociceptive stimuli compared with non-noxious tactile stimuli. Recent magnetic resonance imaging (MRI) data supports this observation and suggests that early procedural pain in very preterm infants contributes to impaired brain development (Brummelte et al., 2012; see also Grunau, Chapter 4, this volume). It is possible that the anatomical alterations observed in infants exposed to excessive nociceptive inputs may underpin some of the functional differences in subsequent nociceptive processing.

## Magnetic resonance imaging

MRI has revolutionized the way we approach pain research. Being non-invasive and non-ionizing, MRI is the ideal technique to investigate the anatomical (e.g. structure and maturation) and functional (e.g. activity and connectivity) networks of the brain involved in the CNS processing of sensory stimulation during early human development.

The transient subplate zone (Kostovic and Molliver, 1974) is one of the main signs of cortical immaturity (Kostovic and Vasung, 2009) and is significant for the normal development of the human

telencephalon, which subsequently develops into the cerebral cortex and basal ganglia (Kostovic and Rakic, 1990; see also Fitzgerald, Chapter 8, this volume). From the subplate grows the thalamo-cortical and cortico-cortical connections (Kostovic and Rakic, 1990), with its neurons contributing to the first evoked potentials from 24 weeks of gestation (Hrbek et al., 1973). Standard MRI techniques allow for the assessment of brain development in infants. Highly sensitive assessment of grey and white matter and the differentiation of myelination in white matter can be visualized. *In vivo*, the transient subplate zone can be seen as an area of hypointensity on magnetic resonance images (Prayer et al., 2006), but after 32 weeks of gestation, the transient subplate zone becomes less visible (Kostovic and Vasung, 2009).

Functional MRI (fMRI) is a non-invasive technique that assesses cortical activation. The most commonly used contrast method is blood oxygen level-dependent (BOLD) imaging. BOLD measures the magnetic change in haemoglobin between the oxygenated and deoxygenated states that accompany neuronal activity (Logothetis and Pfeuffer, 2004; Ogawa et al., 1998), but it is important to be aware that BOLD measures dynamic changes in blood flow and is not directly linked to neural activity. In newborns, most fMRI studies have focused on the visual system, and have demonstrated that visual activation can be obtained in sedated infants (Souweidane et al., 1999). The ability to view abnormal decreases in visual activity (Panigrahy and Bluml, 2007), asymmetric, or absent activations (Bernal and Altman, 2004) makes fMRI a feasible tool to view the visual cortex in disease (Seghier and Huppi, 2010). This could be extrapolated to other neonatal conditions, possibly including the assessment of pain. The non-invasive nature of fMRI allows for repeated scanning in children and longitudinal studies investigating the development of neural networks can be achieved.

In the MRI scanner, neonates and infants are asleep, either naturally or with sedation, and this is one of the major limitations of fMRI—due to the lack of cooperation, tasks involving active participation cannot be performed (Souweidane et al., 1999). However, even asleep, infants show distinct brain activations to cognitive (Redcay et al., 2008) and sensory (Seghier et al., 2006) passive tasks. A more recent discovery is the fluctuation in BOLD fMRI response to intrinsic neuronal activity (Fox and Raichle, 2007). Collecting fMRI data during periods of quiet rest (i.e. without any task) have revealed strong anatomical and functional connections forming a resting-state network (RSN) in the absence of external stimuli (Raichle and Snyder, 2007). Resting-states in infants born preterm or at term have found five consistent RSN cortical ‘hubs’: the primary visual cortex; bilateral sensorimotor areas; bilateral auditory cortex; a network including the precuneus area, lateral parietal cortex, and the cerebellum; as well as an anterior network that incorporated the medial and dorsolateral prefrontal cortex (Fransson et al., 2007). With resting-state networks being identified in healthy infants there is a growing interest in evaluating network alterations in infants with brain injury (Seghier and Huppi, 2010).

In neonates, there is great potential for the various MRI techniques to elucidate the higher CNS processing of noxious stimuli. RSNs in healthy neonates do not entirely correspond to those commonly found in adults (Fransson et al., 2011). Assuming that the cortical hubs denote areas involved in tasks requiring high information processing (Sporns et al., 2007) some reorganization of RSNs must occur between birth and adulthood. It is proposed that cortical hubs in infants may be dominated by processes involving

reflexive behaviour, and those in adults centred toward complex, adaptive behaviour (Fransson et al., 2011).

While MRI has been extensively used in adult pain studies, and specific network disruptions have been described in several adult pathologies including chronic back pain (Baliki et al., 2008), its application in children has only recently begun and to date has not been used to advance our understanding of infant pain. In adults, pain studies utilizing fMRI have involved healthy volunteers or patients. Despite the variability in individual experience, a central 'pain matrix' has been described with some areas of the brain showing consistent patterns of activation following noxious stimulation (Seifert and Maihofner, 2009). These brain areas include, but are not limited to, the thalamus, primary somatosensory cortex (S1), secondary somatosensory cortex (S2), insula, forebrain, and anterior cingulate cortex (ACC) (Tracey and Mantyh, 2007) and involves areas traditionally involved in modulating the cognitive (Apkarian et al., 2004) and emotional (Becerra et al., 2001) aspects of pain perception.

To date, there is only one MRI study investigating the processing of noxious stimuli in children (Hohmeister et al., 2010). Cerebral pain response in children and adolescents aged 11 to 16 years were compared in children with experience of a neonatal intensive care unit (NICU) born preterm or at term, and term born children without NICU experience. Preterm but not term NICU children displayed an exaggerated noxious-specific response compared with controls when stimulated with moderately painful heat stimuli. Brain regions, which classically form part of the adult pain matrix, were activated during noxious stimulation but were not observed during non-painful warmth stimulation. Further, ex-preterm children displayed an increased sensitization to painful stimuli without habituation. This would suggest that in the long term, previous experience of NICU might cause neurodevelopmental changes and cause an alteration in some aspects of nociceptive processing (see also Hermann, Chapter 40, this volume).

A recent imaging development may begin to disclose the reorganization of cortical hubs. Diffusion tensor imaging (DTI) makes it possible to visualize the connections between different brain regions by measuring changes in the diffusion of water in white matter tracts (Alexander et al., 2007). DTI can identify differences between normal and abnormal tracts, and when combined with fMRI studies can help understand the structural connectivity between different brain regions (Hüppi and Dubois, 2006). With resting-state functional connectivity being based, but not exclusively, on direct anatomical connections (Damoiseaux and Greicius, 2009), the assessment of the functional and structural relationships in the infant brain may begin to be investigated.

## Conclusion

The measurement of evoked brain activity in response to nociceptive stimuli in preterm and term born infants may help validate existing behavioural, somatic motor, and autonomic measures of nociception. In addition, these techniques may help in the development of more robust clinical tools for measuring infant pain. This brain-oriented approach to understanding nociception must be considered alongside the existing body of literature that characterizes the clearly observable neonatal behavioural and physiological responses to noxious stimulation. It would be ideal to develop a specific neural biomarker that is a direct correlate of pain experience, however, in the absence of language this is out of our grasp.

Any measure of activity in the CNS following a noxious input in non-verbal patients, be it behavioural, autonomic, or neurophysiological is ultimately a surrogate measure of the experience and cannot tell us what an infant feels. Nevertheless, direct measurement of brain activity may further our understanding of how noxious events are processed by the infant nervous system.

## CHAPTER 40

---

# Sensory processing and neurophysiological evaluation in children

Christiane Hermann

### Summary

Traditionally, pain in children is assessed by behavioural observation and by self-report with a focus on perceived pain intensity. In this chapter, more recently developed standardized psychophysical procedures to assess abnormalities in sensory and pain processing and non-invasive neurophysiological methods to unravel the neuronal mechanisms underlying the experience of pain are described and how they have been used for investigating paediatric pain. For both sensory and neurophysiological assessment methods, the underlying assumptions and theoretical underpinnings are outlined. Following a brief overview of commonly used measures and methods, methodological issues are addressed that need to be considered when planning to use such methods and when interpreting the obtained findings. Finally, empirical examples are reviewed that highlight the use of these techniques for addressing major research questions such as the development of pain processing and changes in sensory and pain processing associated with chronic paediatric pain.

### Introduction

The International Association for the Study of Pain (IASP) defines pain 'as an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage' (Merskey and Bogduk, 1994, p. 210). Accordingly, sensory processing represents a core component of the pain experience. Pain needs to be distinguished from nociception. Nociception entails all physiological processes involved in the transduction of nociceptive (i.e. noxious or potentially tissue-damaging) input by receptors, and the peripheral and central neuronal activity involved in the subsequent processing of nociceptive input. By contrast, pain is a complex subjective experience that is correlated with nociceptive activity, but is not fully accounted for by it. Dating back to the nineteenth century, psychophysics has evolved as the scientific study of the relationship between physical stimuli (e.g. visual, auditory) and the subjective perception they induce. For the sensory evaluation in pain states, a variety of psychophysical methods, often referred to as quantitative sensory testing, have been developed that allow quantification of an individual's subjective response to painful and non-painful stimuli. Although abnormal psychophysical

findings have been related to specific neuronal mechanisms, such interpretations remain putative as the neuronal substrate is not directly assessed.

For investigating neuronal mechanisms of pain, many neurophysiological methods ranging from single-cell or nerve fibre recordings to neuroimaging are available. Here, the focus lies on non-invasive neuroimaging methods such as near-infrared spectroscopy (NIRS), electroencephalography (EEG), and functional magnetic resonance imaging (fMRI) which have been used for studying paediatric pain. Neurophysiological methods for the diagnosis of disease-related pathology will not be addressed.

### Quantitative sensory testing

Over the past 25 years, quantitative sensory testing (QST) has been developed as a method to systematically assess the functioning of sensory and pain pathways. Interest in QST originally grew from efforts for a better diagnosis and mechanism-based understanding of neuropathic pain. Neuropathic pain is of neurogenic origin and arises as a direct consequence of lesions or diseases of the somatosensory system (Treede et al., 2008; see Walker Chapter 21, this volume). It is characterized by various symptoms and signs such as sensory loss, paraesthesias, spontaneous ongoing or paroxysmal pain, and stimulus-evoked pain presumably resulting from pathological somatosensory functioning. The traditional clinical exam of these symptoms has limitations as it is mostly qualitative in nature and lacks standardization of stimulation and measurement (Hansson et al., 2007).

QST has been derived from experimental psychophysical methods. Traditionally, psychophysical procedures can be divided into two broad classes depending on whether it is the stimulus or the response that is the primary dependent variable (Gracely, 2006). Response-dependent methods assess individuals' variable responses to a predefined set of stimuli. Examples are almost all methods used for measuring suprathreshold pain such as rating scales. Stimulus-dependent psychophysical methods entail the administration of varying stimuli with a fixed response and it is stimulus intensity that is measured. Typically, such stimulus-dependent methods are used for determining thresholds. Yet, they also allow suprathreshold pain assessment such as pain tolerance. For determining thresholds, three classical psychophysical procedures are established.

*Method of limits (MLI):* this method entails the administration of stimuli of varying intensity until the subject notes a certain sensation and indicates this verbally or behaviourally. Usually, stimuli are delivered in ascending series, the subject's response stops further increase in intensity. Sensory detection and pain thresholds are defined as the stimulus intensity required to evoke a given sensation (e.g. touch, warmth) or pain, respectively. Whereas sensory detection thresholds rely on discriminating the presence versus absence of a specific sensation, pain thresholds are not only influenced by perceptual sensitivity, but also by the given verbal label and the subject's pain labelling behaviour and the ensuing response bias (Gracely, 2006). In order to reduce expectancy or habituation effects, it is often recommended to use both ascending and descending series. MLI is reaction-time dependent (Yarnitsky and Ochoa, 1990). Most likely, this accounts for thermal thresholds being about 1.5°C higher when determined by MLI as compared to reaction-time independent methods (e.g. Defrin et al., 2006; children: Meier et al., 2001). Despite this limitation, MLI is frequently used because instructions are simple and it is less time-consuming than other procedures. There are reaction time-independent MLI variants. The method of levels entails the administration of stimuli with predefined intensity and the subject's response is recorded. Depending on the subject's positive or negative response, stimulus intensity is systematically either decreased (following a positive response) or increased (following a negative response) until it converges onto the threshold (Meier et al., 2001; Yarnitsky et al., 1990). Stimulus intensity can either be changed in absolute steps or in steps of modality-specific, just noticeable, differences (Yarnitsky, 1997). Reaction-time independent measures are more reliable than reaction-time dependent measures, but require more trials (Yarnitsky, 1997).

*Method of constant stimuli:* similar to MLI, the subject is exposed to a set of stimuli with predefined intensity above and below the threshold of interest. However, these stimuli are presented randomly and the subject is asked to indicate whether or not the stimulus evoked a certain sensation. The threshold is defined as the intensity that the subject reports as the sensation of interest in 50% of the trials.

*Method of adjustment:* unlike MLI, this method requires the subject to directly adjust stimulus intensity until a certain sensation occurs. This procedure has to be repeated many times. Aside from the long duration, it is disadvantageous in that some of the stimulation devices for certain pain modalities do not allow the subject to control stimulus intensity.

In most cases, QST protocols exclusively rely on MLI for determining sensory detection and pain thresholds; mostly for practical reasons, such as keeping the duration of the testing within reasonable limits. Length of testing is an issue because the subject should be alert and awake and motivated to cooperate with the experimenter.

## QST measures

### Sensory modalities

Quantitative sensory testing does not refer to defined set of measures. QST measures can broadly be categorized as static or dynamic (Arendt-Nielsen and Yarnitsky, 2009). Threshold measures (e.g. detection, pain) and pain magnitude ratings for a given stimulus are typically considered as 'static' and are used for assessing the basal state of the somatosensory system. Threshold determination

is helpful for detecting sensory losses and gains such as altered pain sensitivity (hyperalgesia, allodynia, hyperpathia). Including suprathreshold stimuli is important because hypersensitivity can be observed if thresholds are reduced, elevated, or unchanged. 'Dynamic' measures require activation of the pain system such that possible changes in specific mechanisms of pain processing become evident. For example, sensitization to nociceptive input is a key factor in the development of chronic pain. Such sensitization occurs in the peripheral and the central nervous system (Woolf, 2011). In humans, temporal summation (i.e. the increase in perceived pain intensity upon prolonged or repetitive painful stimulation), is considered to represent a perceptual correlate primarily of central sensitization (e.g. Granot et al., 2006). Accordingly, some QST protocols include measures of temporal summation. The testing of descending pain inhibitory mechanisms using procedures of painful counter-irritation is another example of a dynamic QST measure.

Comprehensive QST protocols usually include the testing of different sensory modalities such as thermal, touch, pressure, and vibratory stimuli. For obvious reasons of impracticability and problems of standardization, chemical stimulation is not included. Testing different sensory modalities allows the assessment of the integrity of different types of receptors, peripheral nerve fibres and information integration within the central nervous system. Mechanical stimuli such as light touch, pressure, or punctate stimuli activate A $\beta$ , A $\delta$ , and C fibres (see Table 40.1; Walk et al., 2009). The processing of warm and heat stimuli is dependent on C-fibre activation, cold sensations and noxious cold involve A $\delta$ -fibre and C-fibre activity, respectively. The processing of painful stimuli is mediated both by modality-specific and convergent pathways (Craig, 2003). Hence, pain sensation is the result of central integration of sensory non-nociceptive information and nociceptor input (Defrin et al., 2002). Accordingly, correlations between (supra-)threshold measures across modalities are typically low (e.g. Bhalang et al., 2005). Indeed, factor analyses of different pain modality measures (e.g. heat, ischaemic, pressure, electrical) revealed separate factors each representing a sensory modality (Hastie et al., 2005; Neziri et al., 2011a). In addition, measures of temporal summation loaded on a separate factor, supporting the distinction between static and dynamic measures (Hastie et al., 2005).

### Sensory testing site

When performing QST, the choice of testing sites is important. The obtained values vary considerably between different body regions (e.g. Defrin et al., 2006; children: Hogeweg et al., 1996; Meier et al., 2001; Meh and Denislic, 1994). In one of the most comprehensive studies in healthy adults, QST was performed bilaterally on the face, and at the hand and foot (Rolke et al., 2006b). Similarly, in children, while no left-right differences were observed, sensitivity was highest in the face and lowest in the foot and, with intermediate values in the hand (Blankenburg et al., 2010). Presumably, this region-specific sensitivity is accounted for by differences in innervation and/or thickness of the epidermis. However, these differences, at least for thresholds obtained by MLI, may also be a result of reaction-time-dependent threshold determination. If the method of levels rather than MLI was used, differences in sensitivity between body regions such as foot versus upper body were no longer observed, at least for thermal stimuli (Defrin et al., 2006). Although, in healthy subjects, thermal pain sensitivity does not

**Table 40.1** Overview of the QST measures included in the German Research Network on Neuropathic Pain (DFNS) QST protocol (Rolke et al., 2006) as used in a large sample of healthy children and adolescents for determining normative reference values (Blankenburg et al., 2010)

Static measures	QST parameter	Peripheral nerve fibre	Testing procedure	Testing device
<b>Thermal</b>				
Cold	Detection threshold (CDT)	A $\delta$	MLI (descending)	Computer-controlled contact heat probe (e.g. TSA II, MEDOC, Israel, or MSA, SOMEDIC, Sweden)
	Pain threshold (CPT)	C, A $\delta$	MLI (descending)	
Warm/heat	Detection threshold (WDT)	C	MLI (ascending)	
	Pain threshold (HPT)	C, A $\delta$	MLI (ascending)	
Cold/warm	Thermal sensory limen (TSL)	C, A $\delta$	Alternating warm/cold stimuli	
	Paradoxical heat sensations (during TSL)		Verbal report	
<b>Mechanical</b>				
Cutaneous punctate				
blunt	Detection threshold (MDT)	A $\beta$	MLI (ascending + descending)	von Frey filaments
sharp	Pain threshold (MPT)	A $\delta$ , C	MLI (ascending + descending)	Calibrated pinpricks (N=7; 8–512 mN)
Deep pressure	Pain threshold (PPT)	A $\delta$ , C	MLI (ascending)	Pressure algometer
Vibration	Detection threshold (VDT)	A $\beta$	MLI (descending)	Tuning fork
<b>Dynamic and other measures</b>				
<b>Mechanical</b>				
Sharp	Pain sensitivity	A $\delta$ , C	Numerical pain intensity ratings for all 7 pinpricks (5 repetitions each in pseudo-randomized order) Mean pain rating of 5 series of repetitive stimuli relative to mean pain rating of 5 single stimuli	Calibrated pinpricks (N = 7 with intensities 8–512 mN)
	Wind-up ratio (temporal summation)	A $\delta$ , C		
Dynamic light touch	Dynamic mechanical allodynia	A $\beta$	Mean numerical pain rating for the 3 touch intensities	3 levels of force: cotton wisp, cotton wool tip, brush

MLI = method of limits.

seem to vary between different parts of the hand (i.e. dorsum, finger, thenar eminence), its interindividual variability is lowest at the thenar eminence, thus facilitating use of this site for normative reference data (Hagander et al., 2000).

### Comprehensive standardized QST protocol example

QST in research and in clinical practice requires standardized procedures that promise sufficient reliability, allow comparisons across studies, and reference to norms (e.g. Walk et al., 2009). Most recently, the German Research Network on Neuropathic Pain (DFNS) compiled a battery of tests for sensory loss (small and large fibres) and sensory gain (hyperalgesia, allodynia, hyperpathia) (Rolke et al., 2006b). In two sensory modalities (mechanical, thermal), and bilaterally at three measurement sites (face, hand, foot), both static (detection and pain thresholds) and dynamic (e.g. temporal summation) QST parameters are assessed in a fixed order within one session with detection thresholds determined prior to pain thresholds and suprathreshold measures. Table 40.1 gives a more detailed overview of the obtained QST parameters. The DFNS QST battery is unique as it is the only QST battery for which data in healthy adults, different pain populations and children (Blankenburg et al., 2010, 2011) have been obtained.

### Psychometric considerations: normative QST data

The clinical usefulness of QST depends on relating individual QST findings to reference data. For the DFNS QST battery, normative

data are available for both healthy adults (Rolke et al., 2006b; for a similar protocol see Neziri et al., 2011b) and children (Blankenburg et al., 2010). These data for children compare fairly well with previous reports for selected measures in healthy children using similar instructions and devices (e.g. Hilz et al., 1996, 1998a, 1998b; Meier et al., 2001). However, values can differ when compared to studies using at least slightly different procedures and smaller samples with a greater age range (e.g. Thibault et al., 1994; Walker et al., 2009). By comparing the patient's profile of sensory losses and gains to such normative data, absolute references can be made (Magerl et al., 2010). Alternatively, relative references are possible. Neuropathic pain often affects only one side of the body. In light of the lack of left–right differences in healthy individuals, the unaffected side can then be used as a within-subject (relative) reference and allows characterization of the pattern of disturbed sensory functioning on the affected side (e.g. Kemler et al., 2000).

### Psychometric considerations: reliability of QST

Aside from the availability of normative data, adequate reliability is another prerequisite for validity and clinical usefulness of QST. In their review of the literature, Siao and Cros (2003) concluded that reproducibility of QST findings varied greatly across studies depending on study methodology, sample size, type of study sample, number of examiners, and retest interval. More recently, in healthy adults and patients, retest reliability both for comprehensive QST batteries or thermal measures was reported as good, at least

for retest intervals ranging between 1 to 2 days and up to 3 weeks (e.g. Agostinho et al., 2009; Geber et al., 2011; Heldestad et al., 2010; Moloney et al., 2011; Wylde et al., 2011). In children, retest reliability has not been systematically investigated in sufficiently large healthy and patient samples. Determination of pressure pain thresholds has excellent retest reliability in children with orthopaedic disorders, at least when measured on the same day (Nikolajsen et al., 2011). Similarly, retest reliability for sensory detection thresholds is good (Hilz et al., 1996; Thibault et al., 1994).

In most studies, retest reliability has been determined by computing correlations, the coefficient of variation, or by comparing the means for test–retest measurements. However, these statistical procedures only determine the strength of association, but not agreement (Bland and Altman, 1986). In addition, these tests are based on groups and cannot be applied when deciding on the clinical significance of findings. Derived from the Bland–Altman graphical procedure for determining agreement between measurement methods, the coefficient of repeatability is a measure of normal day-to-day variability, thus providing limits of normal variation (Bland et al., 1986). For example, in a study in healthy adults, normal limits for heat pain threshold (thenar) ranged between 39.5°C and 51.9°C and the coefficient of repeatability was 5.6 °C, i.e. a difference between heat pain thresholds measured on different occasions in the same subject must exceed this magnitude in order to be considered a true difference (Sand et al., 2010).

Since QST is performed by an examiner, interrater reliability is also important. In adults, for the DFNS QST battery, good interrater reliability has been demonstrated both for computer-assisted (thermal) and manually obtained (mechanical) QST parameters (Geber et al., 2011). Notably, the experimenters had undergone extensive training at one centre. In other studies, interrater reliability was substantially lower (e.g. Peters et al., 2003). Similarly, in healthy children, interrater reliability for pressure pain is satisfactory, but lower than retest reliability (Nikolajsen et al., 2011).

Overall, both retest and interrater reliability of QST in children and adolescents requires systematic empirical evaluation. In order to maximize reliability, examiners should follow a highly standardized measurement protocol and be sufficiently trained.

### Modulating influences on QST measurement outcomes

Being a psychophysical procedure, QST relies on the subject's perception and response behaviour. Hence, procedural, contextual and interindividual factors may influence the outcome of QST and further underline the necessity for standardization.

#### Procedural and methodological influences

QST parameters are typically determined by calculating the mean of several ( $N = 3-7$ ) trials in order to yield more reliable estimates. In one of the few studies testing this assumption, cold, but not warm detection and cold pain thresholds significantly decreased from the first to the second trial with no further change across six additional trials (Agostinho et al., 2009). Heat pain threshold strongly increased from the first to the sixth trial; such habituation to painful heat is mediated by peripheral and central processes (Greffrath et al., 2007). The order of the tests may also be relevant. For example, mechanical pain sensitivity was higher and mechanical pain threshold lower when thermal testing preceded mechanical testing as opposed to when mechanical testing was

performed first (Grone et al., 2012). For the thermal modality, no order effects were observed. Initial assessment of pain threshold may also exert a confounding influence on the determination of detection thresholds, at least for thermal stimuli (Heldestad et al., 2010). Especially for thermal testing using contact heat, starting temperature (e.g. Hilz et al., 1995), rate of the temperature increase (e.g. Yarnitsky et al., 1990) and size of skin area (e.g. Khalili et al., 2001) influence the obtained values due to spatial and temporal summation (cf. Jorum and Arendt-Nielsen, 2003). Furthermore, room and skin temperature can have an effect (Hilz et al., 1995; Strigo et al., 2000).

#### Contextual influences

While it is well established that pain responses are modulated by the psychosocial context in which they occur, surprisingly little is known about how these factors impact on QST findings. We observed that mothers' presence during QST testing decreased children's pain sensitivity although mothers only observed the testing from a distance and did not interact with their children (Hohmeister et al., 2009; Zohsel et al., 2006). This modulating influence could be accounted for by perceived social support and/or by distraction. Situationally induced anxiety may also exert a modulating influence. For example, in children undergoing thermal, pressure, and cold pain tasks anticipatory anxiety accounted for about 30% of variance in pain report across tasks (Tsao et al., 2004). By contrast, pain-related coping including catastrophizing does not affect QST results in children (Blankenburg et al., 2011). Biological variables such as circadian rhythms may also modulate QST findings. Very few systematic studies exist, but did not confirm robust circadian patterns of heat pain thresholds (e.g. Bachmann et al., 2011).

#### Interindividual age-related differences

In adults, age and gender influence QST results (e.g. Neziri et al., 2011b). Healthy participants older than 40 years of age as compared to younger participants had significantly higher detection and pain thresholds except for mechanical pain sensitivity measures (Rolke et al., 2006a; see also Hilz et al., 1998a; Meh et al., 1994). Whether sensory and pain sensitivity undergoes a developmental change during childhood and adolescence is less clear. In a first study using the DFNS QST battery, young children (6–8 years) had higher thermal and detection thresholds and lower heat, pressure and mechanical pain thresholds when compared to older children (9–12 years) and adolescents (13–16 years) with the latter two groups not differing significantly (Blankenburg et al., 2010). Yet, in a follow-up study comparing exclusively 7- and 14-year-olds (Blankenburg et al., 2011), the age effect for warmth and mechanical detection thresholds was not confirmed, an age-related increase in pain thresholds was again observed and is consistent with previous reports (e.g. Haslam, 1969; Hogeweg et al., 1996). Earlier studies also found detection thresholds to be age-insensitive; however, most of these studies focused on only one sensory modality, and were limited in sample size and age range (e.g. Hilz et al., 1996; Meh et al., 1994; Thibault et al., 1994). Undoubtedly, somatosensory and pain processing undergoes functional maturation, especially during the first year of life (Fitzgerald, 2005). Whether such developmental changes in somatosensory functioning and pain processing continue during childhood and adolescence, is less clear. Importantly, it cannot fully be ruled out that QST in young children may also be less reliable due to the reaction-time dependence of many QST measures, and due to the fact that QST parameters do not only

reflect sensory sensitivity, but also entail a response bias component (Gracely, 2006). Possibly, this response bias, rather than the actual sensitivity, may change throughout childhood and adolescence.

### Interindividual sex-related differences

In healthy adults undergoing QST, females have significantly lower pain thresholds than men, whereas no effect of sex on detection thresholds was observed (Rolke et al., 2006a). This sex-related difference in pain sensitivity is consistent with conclusions of an earlier meta-analysis on sex-related differences in pain sensitivity (Riley et al., 1998). In youth, few studies have systematically addressed this issue. In a large cohort of about 175 healthy children and adolescents between 6 and 16 years old, girls had significantly lower detection for thermal, pressure, and vibratory stimuli and lower thermal and pressure pain thresholds, whereas no sex-related differences with regard to mechanical stimuli was observed (Blankenburg et al., 2010). By contrast, in a follow-up study of 7- and 14-year olds, no sex differences in pain sensitivity emerged, girls had only lower warmth detection thresholds (Blankenburg et al., 2011). Similarly, no sex differences with regard to pressure pain thresholds were observed in children with orthopaedic disorders (Nikolajsen et al., 2011). Blankenburg et al. speculated that puberty and the concomitant hormonal changes presumably account for the emerging sex differences in pain sensitivity in adulthood. However, a recent meta-analysis of the experimental literature concluded that even in healthy adults, there is no clear and consistent pattern of sex differences in pain sensitivity (Racine et al., 2012a). One explanation may be that rather than biological sex differences, it is psychosocial factors that determine whether or not sex differences are observed (Racine et al., 2012b). Specifically, gender role stereotypes may be particularly important in determining one's response to painful stimulation (Alabas et al., 2012). This could at least partially explain why sex differences in pain sensitivity are not consistently found both in adults and in youth.

Related to the issue of possible sex difference, it has been suggested that subjects' responses especially to painful stimuli may depend on the sex of the experimenter. While such an influence of experimenter sex has been documented in some studies, Racine et al. (2012b) concluded that the available empirical literature in adults does not support a clear and consistent pattern of influence. In children and adolescents, the issue of experimenter sex influencing QST measurements has not been systematically addressed.

### Use of QST in children and adolescents

QST is feasible in children as young as 6 years of age (Blankenburg et al., 2010; Hogeweg et al., 1996). Thermal detection thresholds have even been measured in preschool children at the age of 4 years (Hilz et al., 1996). In children, QST studies have focused on three research questions. Specifically, altered sensory and pain processing has been studied in the context of:

- ♦ Chronic pain problems with or without putative sensory abnormalities.
- ♦ Diseases with an increased risk for neuropathic pain.
- ♦ Delineating the impact of neonatal pain.

Chronic paediatric pain is associated with enhanced pain sensitivity as indicated by lowered pain thresholds and augmented temporal summation which, however, does not necessarily affect all sensory modalities (e.g. Walco et al., 1990; Zohsel et al., 2006).

Moreover, QST can be helpful to determine how generalized such altered pain responding is. For example, children with recurrent abdominal pain did not show altered threshold or sensitization in response to somatic pain stimuli as opposed to previously demonstrated visceral pain hypersensitivity (Zohsel et al., 2008b). QST has been performed in children suffering from growing pains. Sensory thresholds for innocuous brush, cold, vibration and deep pressure stimuli were normal, thus there was no evidence for dysfunctional peripheral nerves (Pathirana et al., 2011). Interestingly, children with growing pains perceived these non-painful stimuli as more intense, and had lowered pressure pain thresholds which may reflect disturbed somatosensory processing (Hashkes et al., 2004). Thus far, neuropathic pain in children has not been systematically evaluated using QST. QST can be useful for early detection of peripheral neuropathy in children with diabetes even in the absence of clinical symptoms (Blankenburg et al., 2012; Heimans et al., 1987).

QST measurements have rather consistently revealed that repeated pain experiences during the neonatal period result in long-term altered functioning of the somatosensory and pain systems (e.g. Hermann et al., 2006; Schmelzle-Lubiecki et al., 2007; Walker et al., 2009). QST may also be useful for detecting hypo- or hypersensitivity to normal sensory stimulation which presumably underlies sensory modulation disorder (Bar-Shalita et al., 2009).

## Neurophysiological evaluation

Neurophysiological methods and especially neuroimaging have played a pivotal role in unravelling the neural substrates of pain. Due to the complex nature of pain, it is not surprising that activation of a large distributed functional network of brain regions, often referred to as the 'pain matrix' underlies the experience of pain. According to a meta-analysis of neuroimaging data, experimental pain is most commonly associated with activations in the primary and secondary somatosensory cortex, thalamus, insula, anterior cingulate and prefrontal region (Apkarian et al., 2005). Depending on type of stimulation, task, and other contextual and individual factors, regions such as amygdala, hippocampus, parietal and temporal areas, the cerebellum, and brainstem areas can also be activated. The neural representation of chronic pain differs from that of experimental pain, and chronic pain modulates brain responses to acute pain (e.g. Baliki et al., 2010). For example, the neuronal signature of chronic pain includes brain areas such as the medial prefrontal cortex which is involved in the processing of self-relevant information (for a review, see Apkarian et al., 2009). Neurophysiological methods have helped to identify the neuronal mechanisms of pain modulation by cognitive processes such as attention or pain-related expectations and by emotions (e.g. Tracey and Mantyh, 2007; Wiech and Tracey, 2009; Wiech et al., 2008). Moreover, these methods have been crucial for confirming neuronal plasticity, i.e. changes in the functioning and/or structure of the nervous system, as a core mechanism in chronic pain (Tracey and Bushnell, 2009; Woolf, 2011).

Most recently, in various chronic pain conditions, structural changes such as decreased grey matter density have been observed which, aside from syndrome-specific alterations, seem to commonly affect brain regions such as cingulate cortex, orbitofrontal cortex, insula, and dorsal pons which are involved in sensory-emotional-motivational integration processes and pain regulation (Apkarian et al., 2009; May, 2008). These structural changes are likely to be consequence of repeated pain and can be reversed by successful

treatment (Rodriguez-Raecke et al., 2009; Seminowicz et al., 2011). While there is a wealth of data in adults, relatively few studies have used these methods to study pain processing during childhood. To some extent, this may be explained by not all neurophysiological techniques being easy to use in children.

## Neurophysiological methods used for the study of paediatric pain

In the past two decades, an unprecedented progress in the development of neuroimaging techniques occurred. A thorough review of these techniques is beyond the scope of this chapter. Here, the focus is on methods that have been used for studying paediatric pain.

### Neuroimaging

Generally, neuroimaging methods can be subdivided into those assessing structural, and those assessing functional, changes in the brain. Structural changes (e.g. grey matter density) or changes in structural connectivity between brain regions are measured by voxel-based morphometry and diffusion tensor imaging, respectively (Sava et al., 2009). Functional imaging techniques differ with regard to the parameter that is measured as a proxy of neural activity.

### Electrophysiological techniques

Techniques such as EEG or magnetoencephalography directly measure electrical activity of neuronal assemblies with high temporal resolution (Pizzagalli, 2007). EEG activity recorded on the scalp is presumably generated by excitatory and inhibitory postsynaptic potentials in cortical neurons, hence EEG is not well suited for measuring subcortical activity, and does not yield whole-brain imaging data. Spatial information about the source of the electrical activity has to be inferred by computational models. Due to the high temporal resolution, it is possible to separate event-related, i.e. time-locked brain activity from background EEG oscillation. These event-related potentials (ERPs) are characterized by distinct components, i.e. negative and positive peaks in the EEG waveform, which reflect different aspects of stimulus processing. For example, in response to painful stimulation, somatosensory ERPs typically show an initial negative peak at about 150 ms post-stimulus followed by a positive peak at about 260 ms (N150–P260). The absolute value of this negative-positive vertex response correlates positively with subjective pain intensity (Garcia-Larrea et al., 1997). Later ERP components (e.g. P300) reflect cognitive processes such as attention and memory (Fabiani et al., 2007). Typically, ERPs are derived based on averaging many trials such that time-locked EEG changes can be discriminated from random variations of EEG activity. However, statistical methods (e.g. principal component analysis) can be applied for single trial analysis such as the cortical response to a heel lance (Slater et al., 2010c).

### Indirect measures of neural activity: metabolism, oxygen consumption, and blood flow

Another approach is to record changes in metabolism, oxygen consumption, and blood flow based on the assumption that these are closely related to neural activity. fMRI is based on measuring changes in the ratio of oxygenated to deoxygenated haemoglobin

in the blood and, therefore, is referred to as a blood oxygen level-dependent (BOLD) imaging technique. Oxygen consumption due to increased neuronal activity is followed by an increase in blood flow and blood volume that leads to reduced concentration of deoxygenated haemoglobin and a concomitant increase in the BOLD signal (e.g. Wager et al., 2007). Major advantages of fMRI are the relatively high spatial resolution for localizing changes in cortical, subcortical, brainstem, and even spinal activity, and non-invasiveness that permits its use in children. Nonetheless, fMRI studies in children are challenging because the scanner environment is likely to be experienced as mildly anxiety-provoking, at least initially. Moreover, fMRI recordings are highly subject to movement artefacts and, therefore, require the subject to lie still during the scanning. This can be a difficult task, especially for younger children. The processing of fMRI data requires that individual data are related to a standard template of common spatial coordinates in order to anatomically localize brain activations. The human brain not only grows in size, but also undergoes structural changes from infancy through childhood until adulthood (e.g. Johnson, 2001). Only recently, MRI atlas templates for different age groups have become available that are based on MRI recordings in larger and more representative samples of children and adolescents (Fonov et al., 2011).

Similar to fMRI, near-infrared spectroscopy (NIRS) is a non-invasive imaging technique based on measuring shifts in (de-)oxygenated haemoglobin. Whereas fMRI uses the different paramagnetic properties as recording signal, NIRS relies on the different optical properties in the visible and near-infrared light range (Bunce et al., 2006). Light administered to the scalp is absorbed by tissue and scattered back to the surface. Oxygenated and deoxygenated haemoglobin differ in their absorption sensitivity depending on the wavelength of the light. By using wavelengths maximizing the absorption by (de)oxygenated haemoglobin, measuring the light scattered back to the surface can be used to infer brain activity. NIRS is an especially promising technique for use in children and even infants because it is safe, non-invasive, and can even be performed as part of a clinical exam (Ranger et al., 2011).

## Understanding paediatric pain—evidence from neurophysiological studies

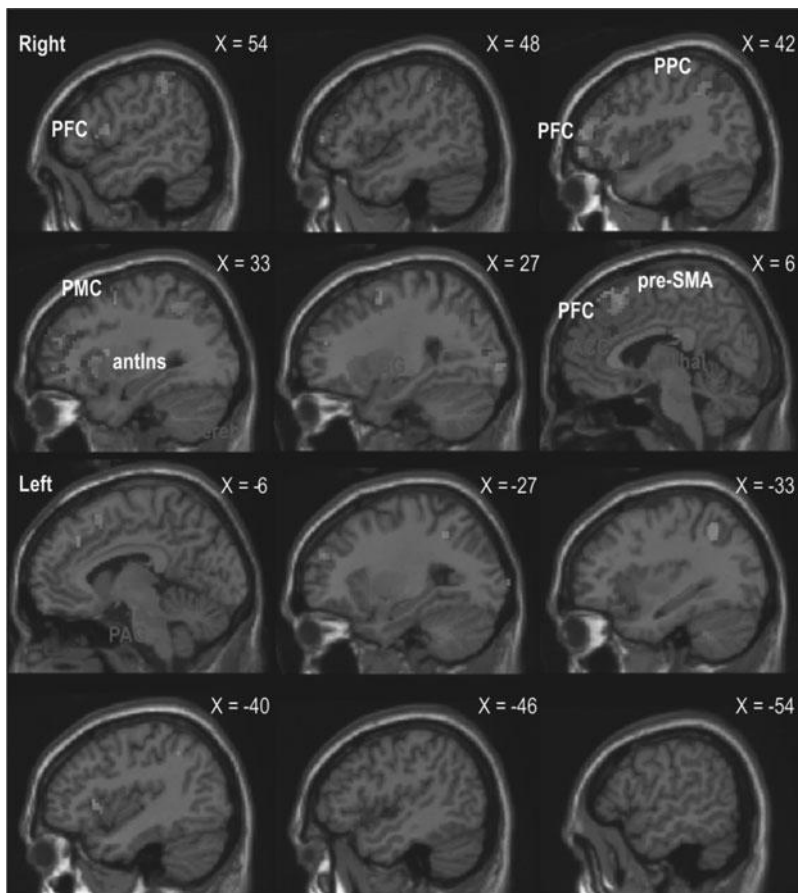

### Evaluation in early life

Neurophysiological methods have fundamentally contributed to unravelling the development of pain processing, especially during early infancy (e.g. Fabrizi et al., 2011; see also Chapter 40 Poorun and Slater, Chapter 39, this volume). In 2006, using NIRS, two studies were the first to demonstrate that, as early as 25 weeks postmenstrual age, an invasive painful medical procedure (e.g. heel lance, venepuncture) as compared to non-painful touch elicits a distinct haemodynamic response in the contralateral somatosensory cortex, hence at this developmental stage thalamocortical pathways are sufficiently mature for cortical processing of nociceptive input (Bartocci et al., 2006; Slater et al., 2006). Also, different intensive care procedures are accompanied by significant cerebral haemodynamic changes (Limperopoulos et al., 2008). Extending these findings, time-locked EEG recordings in infants undergoing heel lance revealed a distinct component consisting of a negative and positive deflection at about 500 ms (N420–P560)

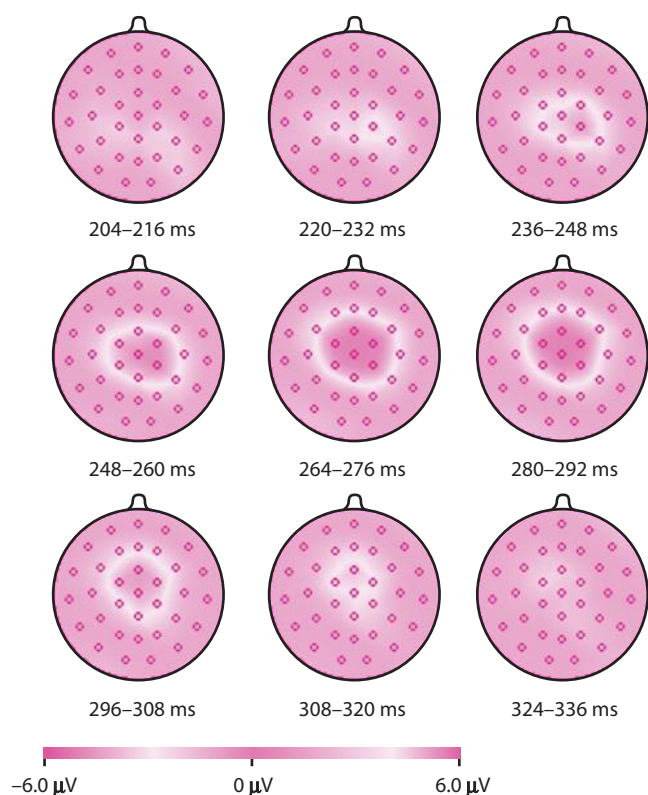

at electrode sites above the somatosensory cortex that is specific for nociceptive input and is larger in preterm compared to full-term-born infants (Slater et al., 2010b, 2010c). Such direct measuring of cortical activity is especially promising for evaluating the efficacy of (non-)pharmacological treatments for infants given that, at this age, pain measurement usually relies exclusively on behavioural observations and physiological parameters (e.g. heart rate, oxygen saturation). For example, in infants, oral sucrose as compared to water did not reduce the cortical response to a painful heel stick despite resulting in an attenuated behavioural pain response (Slater et al., 2010a). Using fMRI, we studied the long-term impact of neonatal pain experiences on brain activation in response to heat pain in school-aged preterm and full-term-born children having undergone treatment in a neonatal intensive care unit (NICU) and control children (Hohmeister et al., 2010). In all three groups, tonic heat pain led to significant activations of brain regions typically involved in pain processing (see Figure 40.1). The preterm, but not the full-term NICU children exhibited significant activations in a number of brain regions (thalamus, anterior cingulate cortex, cerebellum, basal ganglia, and periaqueductal grey) that were not significantly activated in controls. Moreover, the preterms showed significantly higher activations than controls in primary somatosensory cortex, anterior cingulate cortex, and insula. Hence, exposure to pain at a vulnerable stage of the developing pain circuitry, may affect both sensory and affective processing of pain later in life.

## Chronic pain

In chronic paediatric pain, EEG has been used to study cognitive aspects of pain processing and specific pathophysiological mechanisms. In children with migraine and children with recurrent abdominal pain, we recorded somatosensory-evoked potentials in response to painful and non-painful mechanical stimuli which had to be ignored while performing a primary task (Hermann et al., 2008; Zohsel et al., 2008a). Painful stimuli elicited a significantly larger vertex potential (N150–P260) compared to non-painful stimuli. In both pain groups, the P300 in response to both painful and non-painful stimuli was significantly greater than in the controls (see Figure 40.2). This suggests that chronic pain in children is associated with automatic attention to painful and potentially painful stimuli. In migraine, heightened cortical excitability and altered cortical sensory processing have been proposed as pathogenetic mechanisms. Consistent with such concepts, in children with migraine, both cross-sectional and longitudinal studies entailing the measurement of ERPs to sensory stimuli (e.g. visual) and slow cortical potentials suggest altered maturation of cortical information processing (Oelkers-Ax et al., 2008; Siniatchkin et al., 2010). Thus far, only one study has used fMRI in chronic paediatric pain. Children with complex regional pain syndrome (CRPS) were exposed to non-noxious thermal and mechanical stimulation during the acute pain phase and after recovery (Lebel et al., 2008; see also Clinch, Chapter 24, this volume). In the acute pain phase, patients experienced allodynia in the affected extremity and, consistently,

**Figure 40.1** Significant brain activations ( $p < 0.001$ ,  $k \geq 10$ ) during painful tonic heat stimulation in NICU-preterms (red), NICU-full-terms (blue), and the controls (green), superimposed on a normalized T1-weighted brain. X-coordinates of brain slices (in mm) refer to the Montreal Neurological Institute standard brain. PFC = prefrontal cortex; PPC = posterior parietal cortex; PMC = premotor cortex; antIns = anterior insula; Cereb = cerebellum; BG = basal ganglia; pre-SMA = pre-supplementary motor area; ACC = anterior cingulate cortex; Thal = thalamus; PAG = periaqueductal grey. This figure has been reproduced with permission of the International Association for the Study of Pain® (IASP). The figure may NOT be reproduced for any other purpose without permission. This figure is reproduced in colour on the back endpaper.

**Figure 40.2** Between-group difference somatosensory evoked potential (SEP) maps for painful stimuli within the P3 latency window (200–340 msec) comparing children with RAP and healthy controls. The children underwent an oddball paradigm with auditory stimuli as rare targets and painful mechanical stimuli administered to the index finger of the non-dominant hand. The grey shades indicates the difference in magnitude of SEP amplitude between the two groups. Reproduced from Hermann, C. et al., Cortical correlates of an attentional bias to painful and innocuous somatic stimuli in children with recurrent abdominal pain, *PAIN\**, Volume 136, Issue 3, pp. 397–406, Copyright © 2008. This figure has been reproduced with permission of the International Association for the Study of PAIN\* (IASP). The figure may NOT be reproduced for any other purpose without permission.

non-noxious stimuli induced activation of brain regions involved in sensory and cognitive-emotional pain processing. Intriguingly, even after symptomatic recovery, brain activations in response to stimulation of the affected versus the unaffected extremity differed suggesting long-term alterations in the functioning of sensory and pain pathways.

## Conclusion

Psychophysical methods such as QST allow reliable and valid assessment of sensory and pain processing in children and are suitable for bedside examination. Psychophysical measures are useful for characterizing altered sensory and pain processing in chronic pain states and following exposure to painful events. Due to its cognitive demands, psychophysical testing requires children to be at least 6 years of age; hence investigating early development of pain processing is precluded. Here, neurophysiological techniques have substantially advanced our understanding as they allow measurement of neuronal activity without requiring a behavioural response from the child. Nonetheless, neurophysiological studies are still scarce, especially those aiming at unravelling the neuronal mechanisms of chronic paediatric pain. Aside from methodological issues,

this is most likely accounted for by ethical considerations given the relatively high demand on children's compliance with instructions and measurement requirements.

## CHAPTER 41

---

# Measurement of health-related quality of life and physical function

See Wan Tham, Anna C. Wilson,  
and Tonya M. Palermo

### Summary

This chapter reviews the measurement of health-related quality of life (HRQOL) and physical function in paediatric pain populations. We present available data on HRQOL and physical function in children with pain, methods of assessment, details about specific questionnaire and performance-based measures, and recommendations for the use of measures based on available evidence. Because many children and adolescents with pain report impairment in participation in physical activities such as walking, running, and sports, physical functioning is a core target and outcome for intervention, particularly for youth with chronic pain. However, the domain of physical functioning encompasses a number of constructs such as physical fitness, physical activity, and subjective disability, which are interrelated, but represent distinct aspects of functioning. Moreover, HRQOL is a broader concept that subsumes physical and psychosocial function. A wide variety of measurement tools are in use, but no guidelines for measurement have been established. A better understanding of measurement of HRQOL and physical function may enable researchers and clinicians to track children's functional impact and changes in function over time, and to improve the design and testing of potentially effective interventions for children with pain.

### Introduction

It is well recognized that medical conditions and ill health may have significant impact across different areas of a child's life. Pain, particularly chronic pain, may impair school attendance, mobility, self-care, interpersonal interactions, life activities, and community activities (Palermo, 2000). Health-related quality of life (HRQOL) refers to an individual's perception of the impact of an illness, symptoms, and its consequent treatment on their physical, psychological, and social well-being, as well as perception of overall well-being in relation to their health (Eiser et al. 2001). Measurement of HRQOL incorporates assessment of three levels: (1) components of specific domains of functioning (e.g. difficulty walking up stairs), (2) individual domains of functioning (e.g. psychosocial, physical, school, and role

functioning), and (3) an overall assessment of well-being (e.g. global health status). HRQOL scores are often summarized as broad-band scores for physical health and psychosocial health. Integral to the assessment of HRQOL is the domain of physical functioning. Physical functioning refers to actual participation in physical activities and ability to perform physical tasks, as well as the individual's perception of difficulty or restriction in activity participation.

Physical function should be a primary treatment outcome for youth with pain and represents a specific domain requiring detailed assessment. The Pediatric Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (Ped-IMPACT) recommended outcome measures for clinical trials investigating acute and chronic pain in children (McGrath et al., 2008) and identified physical and role functioning as two of the eight core outcome domains. In this chapter, we review approaches for assessment of HRQOL as a multidimensional construct that incorporates the domains of physical and role functioning, and we separately review specific approaches to the assessment of physical functioning. We further describe measures of HRQOL and physical functioning in paediatric pain populations.

### Health-related quality of life and physical function in children with painful conditions

Several examinations of HRQOL in children and adolescents with pain conditions (e.g. headache, sickle cell disease, mixed pain conditions) have found that they report significantly poorer HRQOL in comparison to healthy children (Nodari et al., 2002; Palermo et al., 2002). Moreover, unexplained chronic pain in adolescents has been associated with poor quality of life for the adolescent and his or her family (Hunfeld et al., 2001). Predictors of poor HRQOL within pain populations include the presence of sleep problems (Palermo and Kiska, 2005), fatigue (Berrin et al., 2007), pain-related hospitalizations (Palermo et al., 2002), low socioeconomic conditions (Palermo et al., 2008c) and increasing child age. Little is known, however, about how HRQOL changes over time in youth with pain.

Similarly, physical function has also been fairly extensively studied in youth with various pain conditions primarily to identify how chronic pain can affect children's participation in developmentally appropriate physical and social activities. In one epidemiological study of chronic pain in a community sample of youth (Roth-Isigkeit, et al., 2005), impairments most commonly reported were: sleep problems (53.6%), inability to pursue hobbies (53.3%), eating problems (51.1%), school absence (48.8%), and inability to meet friends (46.7%). Huguet and Miro (2008) examined pain severity including impact from pain using validated measures in a population based sample. They found that 36.8% of youth had some disability, with 31.7% categorized as having a low level of disability and 5.1% having moderate to severe disability. These studies highlight that pain and disability can vary considerably among children with pain.

Prior reviews of HRQOL and function measures

Several recent reviews have provided summaries of measures that have been used to assess HRQOL and physical function in medical populations experiencing chronic pain or chronic illness. Eccleston et al. (2006) identified nine measures of the impact of pain on HRQOL and physical functioning in children with headache, arthritis, abdominal pain, and mixed pain conditions. They concluded that for the majority of the measures, the psychometric evaluations were limited in scope, and had only been used in a few studies.

Palermo et al. (2008b) reviewed 16 measures of HRQOL and functional impairment that have been used with paediatric populations including children with painful conditions. This review classified measures as being well established, approaching well established, or promising. Several well-established measures were found used in pain populations including the Pediatric Quality of Life Inventory (PedsQL; Varni et al., 1999), the Functional Disability Inventory (FDI; Walker and Greene, 1991), and the Child Activity Limitations Interview (CALI; Palermo, et al., 2004). Specific measures are discussed in more detail in later sections. This review called for further research, particularly regarding the validity of HRQOL and functional disability measures in response to interventions, and the clinical utility of changes in these measures (Palermo et al., 2008b).

There is little information available concerning measurement of HRQOL, physical or role functioning in children experiencing acute pain. This is in large part due to the way that measures have been developed in the field where the primary focus has been on the longer-term impact of illness on children. However, we recognize that HRQOL, physical, and role function may be important endpoints in the treatment of children with acute pain as well.

Methods of evaluation of HRQOL and physical function

Starting with the most commonly used method of evaluation, a clinical interview can be used to evaluate physical function. However, the evidence base reviewed here pertains to the use of standardized measures of HRQOL and physical function using validated questionnaires and objective/observational measures of performance. Examples of measurements within each of these methods are reviewed in the following sections; however, this is not intended to serve as an exhaustive review of the literature.

Clinical interview

The cornerstone of the clinical evaluation and assessment of the child in pain is the clinical interview. The clinician uses the

interview to establish rapport, obtain a pain history, and to understand impact of pain on aspects of the child's daily life. Interview probes about school, daily activities, sports participation, recreational and peer activities, and self-care activities can uncover areas of significant limitation in physical function (see Table 41.1). See supplementary online materials for additional interview probes in multiple domains of assessment.

Functional goals are often developed with children and parents around specific areas of limitation tailored to each child's needs. Re-assessment of these allows for monitoring and tracking of patient outcomes. There are limitations to the use of clinical interviews to assess physical function, however, including that questions may be asked in different ways (i.e. lack of standardization), demand characteristics may influence responses, and there is a limited ability to make comparisons across children. Empirical support is not yet available to recommend a standardized clinical interview for assessing physical function in paediatric pain.

HRQOL questionnaires

HRQOL can be assessed on questionnaires that can be generic or condition-specific measures (Palermo et al., 2008b). Generic measures are not intended for a specific population, and allow for comparisons across children with different pain or medical conditions. Condition-specific HRQOL measures, on the other hand, are developed for examination of specific impairments experienced by children with the same health conditions. This may increase sensitivity in capturing the nuances of living with specific conditions. However, condition-specific instruments do not allow for comparative measurements across different illness groups, or between children with and without pain.

Two commonly used, well-established generic HRQOL measures that have been applied to pain populations are the Child Health Questionnaire (CHQ) and PedsQL. The CHQ is a widely used instrument, initially developed for use in healthy children

Table 41.1 Clinical interview questions to assess physical and role function

Domain	Sample question
Overall health status	How would you describe your overall health?
Daily living	Describe a typical day. What is your routine? What activities do you do during the day?
Self-care	What do you do to take care of yourself and your body?
School participation	How often do you attend school? When you go to school, how long do you stay? Do you have any difficulties completing schoolwork?
Community participation	Do you participate in hobbies, like clubs or after-school activities, or church?
Physical activities	Do you participate in sports or other athletic activities? What activities are difficult for you to do because of your pain? What would you like to be able to do that you can't do now?
Activities with peers	How often do you spend time with friends? What do you do with friends?
Activities with family	What activities do you do with your family (parents, siblings)?

(Landgraf et al., 1996). It incorporates 13 domains including psychosocial functioning, physical and role functioning, family cohesion, school and activity limitations, behaviour, self-esteem, and the emotional and time impact on the parent. Broad band measures of physical health and psychosocial health can be derived. This instrument has been used for HRQOL assessment in children with chronic pain conditions such as juvenile idiopathic arthritis and sickle cell disease (e.g. Panepinto et al., 2005; Selvaag et al., 2003). Notable strengths of the CHQ are the broad generalizability across different medical conditions (Bruijn et al., 2009; Krab et al., 2009), widespread international experience (Ruperto et al., 2001), and feasibility via Internet administration (Raaij et al., 2007). Primary disadvantages of the CHQ are the excessive length of the scale in comparison to other HRQOL measures, the more limited range of child self-report (only available for age 10 and above), and that the parent and child versions are not parallel which prohibits direct comparison of parent and child reports.

Another commonly used instrument is PedsQL (Varni et al., 1999). Initially developed to assess HRQOL in children with cancer, it has undergone development and validation as both a core instrument and disease-specific modules within numerous paediatric medical populations. It assesses four core broad-band domains of physical, psychological, social and school functioning. The PedsQL

4.0 has been used for descriptive purposes in general pain populations and in specific pain conditions such as sickle cell disease and fibromyalgia (Dale et al., 2011; Gold et al., 2009; Varni et al., 2007a). It has been used in several intervention studies for outcome assessment (Hicks et al., 2006; Langley et al., 2011). Several disease-specific modules may be relevant for use with pain populations such as the Rheumatology Module (Varni et al., 2002) which includes subscales for pain and hurt, daily activities, treatment, worry, and communication. One unique feature of the PedsQL is the applicability across a wide age range; it has been validated for use from birth to 18 years old, with multiple versions for different ages (Varni et al., 2011). Research on the validity of this measure has been conducted internationally (Amiri et al., 2010; Tsuji et al., 2011) and across several ethnic and racial groups (Limbers et al., 2009). Construct validity was demonstrated by determining responsiveness following medical intervention over time (Varni et al., 1999). Several studies have found that the electronic (e-PedsQL) Internet mode of administration demonstrates equivalent properties to the paper and pencil mode of administration (Varni et al., 2008a; Young et al., 2009). The disadvantage of the PedsQL 4.0 is that the instrument provides a broad assessment of HRQOL and may not be responsive to changes in disease-specific symptoms. Additional details on psychometric evaluation of the generic measures of HRQOL can be found in Table 41.2.

**Table 41.2** Psychometric characteristics of HRQOL and physical function measures

Name of measure	Number of items/ administration burden	Validity			Reliability					Population developed
		Construct	Criterion	Content	Temporal stability	Test–retest	Internal consistency	Sensitivity to change	Interrater reliability	
Child Health Questionnaire (CHQ)	Child: 87 Parent: 98, 50, and 28 (3 versions)	x		x		x	x			Healthy and medical paediatric populations
Pediatric Quality of Life Inventory (PedsQL)	Child: 23 Parent: 23 Short form: 15	x		x			x	x		Paediatric medical populations
Pain Experience Questionnaire (PEQ)	Child: 15 Parent: 12	x		x			x			Paediatric chronic pain
Bath Adolescent Pain questionnaire (BAPQ)	Child: 61 Parent: 61	x				x	x			Paediatric chronic pain
Functional Disability Inventory (FDI)	Child: 15 Parent: 15	x	x		x		x	x	x	Paediatric chronic pain
Child Activity Limitations Interview (CALI)	Child: 21 Parent: 21	x				x	x	x		Paediatric chronic pain
Timed walk task	Up to 10 min to administer	x						x		Healthy and medical paediatric populations
Sit-to-stand task	Approx. 1 min to administer	x						x		Healthy and medical paediatric populations

There are two newer multidimensional measures designed specifically for children with pain conditions: the Bath Adolescent Pain Questionnaire (BAPQ; (Eccleston et al., 2005) and the Pain Experience Questionnaire (Hermann et al., 2008). Although a HRQOL framework was not used to develop these instruments, they both cover a range of constructs important in HRQOL assessment and were designed specifically to assess pain-related interference and functioning. The BAPQ was designed for adolescent and parent report and focuses on assessment of psychosocial, activity limitations, social, and family functioning. The PEQ was based on the Multidimensional Pain Inventory, commonly used in adults with chronic pain, and is a multidimensional pain measure designed for ages 7 and up. Both instruments require additional psychometric evaluation. However, the strengths of both measures are that they were developed for children and adolescents with chronic pain and may capture unique limitations and impact experienced by this population.

There are also HRQOL measures designed for specific paediatric pain populations. For children and adolescents with chronic headaches or migraines, available instruments include The Quality of Life Headache in Youth (QLH-Y) and The Migraine Specific Quality of Life Questionnaire Version 2.1 (MSQ). The QLH-Y assesses the domains of psychological and social functioning, functional status, physical status, and satisfaction with life and health (Langeveld et al., 1996). The MSQ assesses impact of pain on physical, emotional, and social functioning (Martin et al., 2000). Both measures have been validated in relatively small samples. For children with arthritis, the Arthritis Impact Measurement Scales 2 (AIMS 2) and Juvenile Arthritis Quality of Life Questionnaire (JAQQ) have been used as disease specific measures of physical and psychosocial function in children with juvenile idiopathic arthritis (Duffy et al., 1997; Meenan et al., 1992).

### Questionnaires for assessment of physical function

Questionnaires designed to capture activity limitations, restriction, and functional impairment or disability related to pain fall under the domain of physical function. They may provide a more comprehensive examination of areas of impact or disability that may be overlooked by general measures of HRQOL. For the child with a pain condition, measures of physical function may identify specific areas of decreased activity performance secondary to pain that could serve as the goal of intervention. Two generic and five condition-specific instruments of physical function are discussed in the following paragraphs.

Measures of functional impairment that assess subjective perception of difficulty performing activities include the Functional Disability Inventory (FDI) and the Child Activity Limitations Interview (CALI). Both were developed for children and adolescents with chronic pain. The FDI (Walker and Greene, 1991) was initially developed for adolescents with abdominal pain; it has since been used in children with other chronic pain conditions (headaches, musculoskeletal pain; Claar et al., 2006), as a descriptive measure (Kashikar-Zuck et al., 2011), and as a treatment outcome measure (Kashikar-Zuck et al., 2005). The CALI (Palermo et al., 2004; Palermo et al., 2008a) was developed to assess activity limitations associated with chronic pain in broader populations, and to allow for both retrospective assessment and daily prospective assessment in a diary format. It has been factor analysed and has been shown to be responsive to change in treatment outcome research (Palermo et al., 2009). Details of the psychometric evaluation of these measures can be found in Table 41.2.

Condition-specific measures of functional impairment are also available. For example, two measures assessing function in arthritis are the Child Health Assessment Questionnaire (CHAQ; Stephens et al., 2007) and the Juvenile Arthritis Functional Assessment Report (JAFAR). The CHAQ is a valid and reliable measure used to guide clinical decisions for level of assistance for functional impairment and to evaluate functional improvement after intervention (Halbig et al., 2009). The JAFAR has demonstrated good construct validity, reliability and responsiveness (Howe et al., 1991), and has been widely used in juvenile idiopathic arthritis. In the migraine population, the PedMIDAS (Hershey et al., 2004) is a brief measure with promising initial validation, and includes items assessing school, physical, recreation and peer participation.

### Objective and observational measures of physical function

Certain constructs within the domain of physical function, including physical fitness and activity, are traditionally measured with objective and performance-based tools. For example, physical fitness may be measured using oxygen exchange for aerobic or anaerobic capacity, isokinetic machines or force dynamometers that measure torque and strength, and body mass index or skin-fold calipers for body composition. Objective measures of physical activity may include motion sensing devices such as pedometers and accelerometers.

Observational performance-based measures of function provide information about an individual's actual performance on tasks which are typically designed to mimic naturalistic tasks that would be encountered in daily life (e.g. lifting, walking). In rehabilitation settings, performance-based measures of function are routinely used in evaluation and re-evaluation of patients with chronic pain.

In adult pain research, a broad range of observational measurement systems have been developed to assess physical functioning, such as the Sorenson back extension test (Harding et al., 1994), the sit-to-stand (the number of times an individual can move from a seated to a standing position in a 1 min time period), and the timed walk (how long it takes an individual to walk a certain distance such as 10 metres, or how far a person walks in a certain time period such as 2 or 6 min). These measures are administered using standardized conditions (often in a gym).

Observational and performance measures have been used surprisingly little in paediatric pain populations. In juvenile arthritis, standardized measures of fitness such as grip strength have been shown to correlate with self-report measures of physical function (Wessel et al., 1999). Standardized back muscle endurance measures have also been used with youth who have chronic musculoskeletal pain (O'Sullivan et al., 2011). Only one study of which we are aware has utilized performance measures to assess intervention outcome. In this study, improvements were found in adolescents with chronic pain on sit-to-stand and timed walk measures following an intensive interdisciplinary physical therapy and psychological treatment day hospital programme (Eccleston et al., 2003). Observational measures have the advantage of reduced subjectivity compared to self-report. Disadvantages of these measures include some burden in terms of additional time needed to administer the tasks, as well as necessitating training research or clinical staff. At this time, however, the most significant limitation is the lack of available data on any particular performance-based measure of physical function in children with painful conditions.

Physical activity, a specific domain of overall physical function, can be measured via self-report, proxy-report, or via activity monitors that capture physical activity in daily life such as pedometers or actigraphic monitoring devices. This domain of physical function is relevant for acute and chronic pain conditions, as pain is often characterized by limitations in movement and withdrawal from physical activities (Sullivan et al., 2008). Additionally, low levels of physical activity have been associated with the development of pain in adolescents (Skoffler et al., 2008).

Several self- and proxy-report measurement systems, including diary and recall reports, have been developed for assessment of physical activity in healthy adolescents (see review by Sirard et al., 2001). Examples of available measures include the International Physical Activity Questionnaire (IPAQ), which shows adequate reliability and has been validated with objective measures of energy expenditure in adolescents (Arvidsson et al., 2005). Brief physical activity screening measures are also available for use with adolescents (e.g. Prochaska et al., 2001). These measures typically prompt the adolescent to recall a specific time period (e.g. the last 7 days) and estimate the amount of time spent in various levels of activity (e.g. vigorous enough to sweat).

Despite the availability of self-report measures of physical activity, there are few published studies examining these measures in youth with acute or chronic pain. Among youth with musculoskeletal pain, diary reports of physical activity demonstrate less time spent in physical activity compared to healthy controls (Kashikar-Zuck et al., 2010; Tarakci et al., 2011). Similarly, youth with nonspecific musculoskeletal pain reported lower levels of activity using the Youth Activity Questionnaire (Ainsworth et al., 1993), compared to healthy youth matched for age and sex (O'Sullivan et al., 2011). While there are limitations to self-report of physical activity in children and adolescents, particularly among those with chronic pain (Kashikar-Zuck et al., 2010), additional research in this area would provide more information about the impact of pain on physical activity and to understanding of how these measures perform in pain populations.

Activity monitoring or actigraphy typically uses wrist- or hip-mounted accelerometers to track an individual's movements in daily life activities, which may be converted to caloric expenditure. These measures of physical activity provide proxy data on actual movement patterns and have been used in a few studies of adolescents with chronic pain. Two studies have compared adolescents with mixed chronic pain problems (headaches, abdominal pain, and musculoskeletal pain) to matched healthy controls on actigraphic measures of daytime activity, and found lower activity levels and more time spent in sedentary activity among youth with chronic pain (Long et al., 2008; Wilson et al., 2012). In one study of adolescents with juvenile primary fibromyalgia syndrome, between-subject variability in physical activity levels were high; among these untreated youth, higher activity was associated with significantly lower levels of self-reported pain intensity, depressive symptoms, and functional disability (Kashikar-Zuck et al., 2010). Overall, actigraphic measures have been moderately correlated with self-reports of physical functioning among youth with chronic pain. There are various monitoring devices and computer programs that have been developed for research purposes and can be used to assess physical activity (see review of activity monitoring in children and adolescents by Bjornson et al. (2004)). To our knowledge, no published studies have examined physical activity in children experiencing acute or postoperative pain, or in association with acute or chronic

pain management or treatment. There has been too little empirical work performed to date to recommend specific objective measures of functional assessment in youth with pain.

## Outcomes measurement

Enhancing children's functioning is often the primary treatment goal for youth with chronic pain. Re-assessment of HRQOL and function is important for understanding the impact of treatments, both on individuals and on groups. To date, the majority of studies have used HRQOL and function to describe paediatric medical and pain populations, however, there have been limited studies using these tools as outcome measurements after intervention. There are a few paediatric studies that utilized HRQOL as an outcome measure after pharmacologic intervention for rheumatologic conditions (Ruperto et al., 2010). With respect to psychological intervention, similarly, few randomized controlled trials of psychological treatments have measured change in children's physical or role functioning from pre- to post-treatment (Palermo et al., 2010). While psychological interventions are largely found to be effective in reducing pain intensity, a significant gap remains in our knowledge of the effects of psychological interventions on physical and role functioning, especially in randomized controlled trials.

Given the broad range of assessment measures and approaches available, clinicians must make choices to prioritize what information about HRQOL and functioning will be useful to collect when evaluating an individual child with chronic pain and his or her family. Interview and questionnaire reports of HRQOL and physical function should ideally be obtained from self-report if the child is cognitively and physically able to provide it. Parent or caregiver proxy reports can provide additional information on parent perception of the HRQOL and functioning of the child. As there is imperfect agreement between self and proxy report (Varni et al., 2007b), proxy report should be used to supplement assessment of the child, not to replace information provided by self-report. Parent report has some unique correlates; for example, parental perception of HRQOL (rather than child perception) and function has been shown to be associated with children's healthcare utilization (Campo et al., 2002; Janicke et al., 2001).

There are several new developments in measurement of physical function. Most notably, considerable work has been invested in the Patient Reported Outcomes Measurement Information System (PROMIS) funded by the National Institutes of Health. At present, preliminary validation has been conducted on a new measure of pain interference in children (Varni et al., 2010) that can be administered via self-report or computerized adaptive testing. Pain and function are areas identified by PROMIS where ongoing work will continue to advance assessment of health related outcomes in the paediatric pain population.

## Best available evidence to guide current use of assessment tools

A wide variety of methods have been used to measure HRQOL, physical function, physical activity, and physical fitness. Clear guidelines are not presently available for measurement of physical function domains in the paediatric pain population. Further research on psychometric properties of measures and comparative analysis of measurement methods is needed in this area to establish

**Table 41.3** Recommendations for assessment of HRQOL and physical function in children and adolescents with painful conditions

Assessment	Name of measure (acronym)	Reference	Primary scale content
HRQOL–generic measures	Child Health Questionnaire (CHQ)	Landgraf et al. (1996)	Physical functioning, role functioning: emotional/behavioural, role functioning: physical, bodily pain, general behaviour, mental health, self-esteem, general health perceptions, parental impact: emotional, parental impact: time, family activities, family cohesion, change in health
Multidimensional pain-specific measures	Pediatric Quality of Life Inventory 4.0 (PedsQL4.0)	Varni et al. (1999)	Physical, psychological, social, and school functioning
	Pain Experience Questionnaire (PEQ)	Hermann et al. (2008)	Pain severity, pain related interference, affective distress, perceived social support
	Bath Adolescent Pain Questionnaire (BAPQ)	Eccleston et al. (2005)	Physical functioning, social functioning, depression, general anxiety, pain-specific anxiety, family functioning, and developmental functioning
Functional Impairment	Functional Disability Inventory (FDI)	Walker and Greene (1991)	Physical and psychosocial limitations due to pain
	Child Activity Limitations Interview (CALI)	Palermo et al. (2004)	Activity restrictions in daily, personal, recreational, physical, and social activities due to pain

these guidelines. We have made recommendations to guide the use of instruments for measurement of HRQOL and physical function in paediatric pain populations in Table 41.3. We have chosen not to recommend measures within specific pain conditions given the small available evidence base within any one condition. In addition, due to the limited available data on objective and performance-based measures in children with pain, it is premature to recommend their routine use.

## Conclusion

Collectively, information obtained from the clinical interview, questionnaires, and observational measures allow for global evaluation of HRQOL and physical function in the child with pain. Due to the availability of numerous measures, the choice of instrument(s) needs to be guided by measurement quality of the instruments and the goals set by and the clinician and/or the researcher. In examination of the wide range of available instruments, we have identified several research priorities:

- ♦ Validation of HRQOL and physical function measures for use in children with pain conditions requires further attention. At this time it is not clear whether currently available measures are appropriate in the context of acute pain or whether adaptations to existing measures or the development of new measures will be needed.
- ♦ To extend the clinical utility of measures, additional work is required to establish the clinical meaning of changes in scores for individuals. The development of cut-points to indicate clinical severity of the limitation in HRQOL or physical function may be useful for certain measures. For an example, see Kashikar-Zuck et al. (2011) concerning clinical utility of the FDI.
- ♦ There is limited information on any objective or performance-based measure of physical function or activity in children with pain. Additional work is needed with performance-based tasks (e.g. timed walk), activity devices (e.g. actigraphy), and with physical fitness measures (e.g. grip strength) to develop normative data in paediatric pain populations and understand relative

levels of impairment. Moreover, the relationship between subjective measures (questionnaires) and objective performance measures requires specific consideration.

In summary, HRQOL and physical functioning instruments may allow for objective assessment of the global functioning of the child, enable standardized comparison within and across painful medical populations, and provide longitudinal monitoring of outcomes over time and in response to intervention. Applications of HRQOL measurement reviewed by Varni et al. (2005) suggest that standardized measures may improve communication between the health care provider and the child and family as well as improve child and parent satisfaction by actively eliciting information about the child's functioning. Thus, in order to optimize the use of these measures, further research into the potential benefits are needed in paediatric pain populations.

## Case example

Kristy is a 16-year-old female who began experiencing low back pain about 2 years ago. Prior to pain onset, she participated in softball and volleyball at her school, but has now given up these sports activities due to pain. Kristy has missed an increasing number of school days in the past year, which she attributes to worsening pain from sitting for long periods. Her parents report that she is more sedentary than she used to be, spending much time lying down at home. They also note that she often refuses to do household chores that involve lifting. Kristy has begun to avoid interactions with her friends because they often choose activities that involve walking long distances. Currently, Kristy reports that she can go on walks on days when her pain is less intense, but only walks for 20 to 30 min once or twice a week. She also experiences increased pain when walking up and down stairs, and when her pain is severe she will sleep on the couch at night to avoid walking upstairs to her bedroom. Her night-time sleep has been disrupted for the past several months and she is often fatigued during the day.

Assessment that includes a combination of interview questions, standardized measures of HRQOL and physical function in conjunction with performance measures may provide clinically relevant information. The clinical interview could be used to assess in detail Kristy's participation in physical and role activities (e.g. doing family chores at home, attending school, doing things with friends). Specific interview probes could be used with Kristy and her parent(s) to understand Kristy's expectations for activity and role participation and what her individual values are around functional activities. A measure of overall HRQOL, such as the PedsQL 4.0, would provide information about perception of overall health impact, while a measure of pain-related activity limitations or disability such as the FDI or the CALI-21 would provide information about pain impact on functioning that may identify specific intervention targets or goals. Because Kristy reports trouble walking, and a timed 10-metre walk would establish a baseline performance that could be used throughout treatment to assess progress. Additional measures of performance and fitness might be chosen by a physical or occupational therapist.

These measures can provide valuable information to assess Kristy on an individual basis, and to also compare the level of impairment secondary to pain in comparison to other adolescents with pain conditions. Furthermore, the measures can also allow the clinician to track Kristy's progress over time to objectively monitor her level of functioning and assess for changes in impairment if treatment is undertaken.

## CHAPTER 42

# Principles of pain pharmacology in paediatrics

Kim Chau and Gideon Koren

### Summary

Changes during growth and development may profoundly alter the pharmacokinetic and pharmacodynamics profile of medications in children of different ages, and in comparison to adults. Genetic factors can also influence the disposition and action of a drug, and contribute to interindividual differences in clinical response. Safe and effective pharmacological management of pain in neonates, infants, and children requires a thorough understanding of the principles of analgesic pharmacology in paediatric patients. Analgesic dosing regimens should take into account the severity of pain, the age or developmental state of the infant, and the therapeutic window of the drug.

### Introduction

Growth and development differences exist between children and adults and these may profoundly alter the pharmacokinetics and pharmacodynamics of medications in children (Anderson and Palmer, 2006; Kearns et al., 2003). In the past, formulaic approaches were used to determine paediatric drug doses, with some using discrete age points or principles that assume that infant growth is a predictable and linear process. For example, using Young's rule and Clark's rule, a child's dose is based on a mathematical fractionation of the adult dose. To calculate an approximate child's dose, these formulae divide the child's weight (in pounds) by the assumed average weight of an adult (150 lbs) and multiply the fractional result by the adult dose (Munzenberger and McKercher, 1980). With advances and integration of developmental pharmacology into clinical practice, it is now recognized that neonates and infants are not merely 'small adults' and thus, they do not respond to pharmacological therapy in a similar manner to adults (Kearns et al., 2003). When approaching pharmacological decisions in managing pain in paediatric patients, there needs to be an appreciation of the interaction between pharmacokinetics and pharmacodynamics of therapeutics. As a result, factors that must be considered when treating infants and children include:

- ♦ Rate of drug absorption via oral route of administration is slower in neonates than in infants and older children; thus, time to achieve maximal plasma levels is prolonged (Heimann, 1980).

- ♦ Neonates and infants have higher percentage of body weight as water and smaller fat and muscle stores compared to adults; therefore, water-soluble drugs may have larger volume of distribution (Echeverria et al., 1975).
- ♦ They have an anatomically developed liver at birth; however, functional maturation is delayed and as a result, neonates exhibit delayed maturation of hepatic drug metabolizing enzymes compared to older children, until around 6 months of age (Tateishi et al., 1997).
- ♦ The kidney exhibits slower glomerular filtration rate and tubular secretion.
- ♦ Plasma concentrations of albumin and alpha-1 acid glycoprotein are lower than in adults; for some drugs (e.g. sulphonamides) this may result in greater availability of unbound active drugs and thereby, greater drug effect or increased risk of drug toxicity (Heimann, 1980).
- ♦ Neonates have an immature blood-brain barrier (BBB), which may allow increased passage of certain drugs, such as morphine and meperidine, into the brain (Bouwmeester et al., 2003; Way et al., 1965).

Unfortunately, there are still gaps in our understanding of the impact of maturational changes on the clinical pharmacology of most drugs; however, it is abundantly clear that the continuous physiological development of neonates, infants, and children influences the disposition of most drugs (Holford, 1996; Kearns et al., 2003). Therefore, to safely and effectively manage pain in neonates, infants, and young children, a thorough understanding of the principles of pain pharmacology in paediatric patients is essential.

### Developmental paediatric pharmacokinetics

The use of pharmacological agents for the treatment of pain in paediatric patients should be guided by the general principles of developmental pharmacology. Accordingly, paediatric analgesic dosing regimens should take into account the severity of pain and the age or developmental state of the infant (Helms and Barone, 2008), as well as the therapeutic window of the drug, to avoid

dose-dependent toxicities. The traditional empirical approach to determining paediatric drug doses was based on the allometric size scaling principle, whereby pharmacokinetic parameters were based on relative body size and it was generally assumed there is a linear relationship between body mass and body surface area in infants, children, adolescents, and adults (Ritschel, 1980). However, infant growth and development are not always linear processes when growth and age-related changes in body composition and organ function are considered (Kearns, 2000). Therefore, simply scaling an adult dose for infants and children based on body weight or body surface area may result, at times, in either ineffective pain management or severe, unexpected toxicity (Holford, 1996). As such, using a non-linear relationship between weight and drug elimination capacity is more appropriate for determining drug dosing regimens of pain treatments in paediatric patients (Dawson, 1940). Of note, such guidelines are primarily applicable for initiating pain therapy, and long-term maintenance of pain therapy must be individualized and requires consideration of developmental variations in pharmacokinetics and pharmacodynamics. Thus, to safely and effectively manage and treat pain in paediatric patients, a fundamental understanding of the interplay between growth and development on the disposition and actions of drugs is necessary.

### Absorption of drugs

The absorption of drugs administered to neonates and infants is significantly influenced by developmental changes in absorptive surfaces, such as the gastrointestinal tract, pulmonary bronchioles, and skin; these sites of absorption determine the rate and extent of the bioavailability of a drug (Kearns, 2000). Furthermore, the relative amount of drug available for absorption is affected by the intraluminal pH. For example, gastric pH is higher (greater than 4) in neonates compared to older children, affecting the stability and the degree of ionization of a drug, and thus influencing the amount of drug that can be absorbed (Agunod et al., 1969). Therefore, strong acidic drugs, such as penicillin, administered orally have a greater bioavailability in neonates than in older children; whereas, for neonates to achieve therapeutic plasma levels of orally administered drugs that are weak acids, such as phenobarbital, larger doses may be required due to the higher intraluminal pH (Kearns et al., 2003; Koren et al., 1993).

Following birth, neonates experience a marked increase in gastric emptying due to the improvement of the coordination of antral contractions (Gupta and Brans, 1978; Ittmann et al., 1992). This is clinically significant as the rate of drug exposure along the mucosal surface of the small intestine is determined by the transit time of the drug within the gastrointestinal tract. As a result of increased gastric emptying in neonates, orally administered drugs are less well absorbed and more time is required to achieve therapeutic plasma levels of drugs in neonates compared to older children and adults (Heimann, 1980). Although few bioavailability studies have examined the absorption of drugs in infants and older children, it has been suggested that both passive and active transport are fully mature in infants by approximately 4 months of age (Anderson and Holford, 2008; Heimann, 1980).

Delayed maturation or developmental differences in the activity of intestinal drug-metabolizing enzymes in neonates and infants may affect the bioavailability of drugs (Hines and McCarver, 2002), and can alter the systemic absorption of therapeutically active metabolites of certain drugs, such as theophylline. For example,

the intestinal activity of cytochrome P450 (CYP) 1A1 (CYP1A1) is lower during infancy compared to late childhood; however, it appears that the activity level increases with age (Stahlberg et al., 1988). At birth, glutathione-S-transferase (GST) activity is high compared to older children, but decreases during infancy through early adolescence (Gibbs et al., 1999).

Relative to adults, the stratum corneum is thinner and the epidermis is also more hydrated in neonates and throughout childhood, which may result in an increase in percutaneous absorption during infancy (Fluhr et al., 2000). As infants and young children have a greater total body surface area to body mass ratio than adults, topically applied drugs display greater systemic exposure in infants, which may result in toxic effects if the dose administered is not age-appropriately adjusted (Fluhr et al., 2000; West et al., 1981).

Rectal administration of drugs is increasingly being used in infants and young children, but may have greater bioavailability in neonates due to the delayed developmental maturity of hepatic drug-metabolizing enzymes. Conversely, neonates and infants may absorb less drug following rectal administration compared to adults (van Lingen et al., 1999) due to a greater number of high-amplitude pulsatile contractions resulting in greater expulsion of drugs (Di Lorenzo et al., 1995). As absorption and bioavailability of acetaminophen suppositories are unpredictable, and delayed peak plasma concentration is observed compared to oral administration, rectal administration may result in subtherapeutic plasma concentrations (Autret et al., 1993; Goldstein et al., 2008; Rumore and Blaiklock, 1992; see also Anderson, Chapter 43, this volume).

### Distribution of drugs

Developmental changes in body composition are primarily responsible for the age-associated differences in drug distribution. As neonates and infants have relatively larger extracellular and total-body water, coupled with smaller fat and muscle stores compared to adults, when water-soluble drugs are administered, plasma levels in these compartments may be lower (i.e. larger volume of distribution; Echeverria et al., 1975; Siber et al., 1975). Additionally, neonates and young infants have lower amounts of total circulating plasma proteins, such as albumin and  $\alpha_1$ -acid glycoprotein, resulting in an increase in the free fraction of drugs, which influences the availability of the active moiety of drugs (Ehrnebo et al., 1971). The free fraction of highly protein-bound drugs is higher in neonates compared to older children and adults, as foetal albumin has lower binding affinity for weak acids, and there is an increase in endogenous substances (e.g. free fatty acids) with a high affinity for displacing drugs from albumin binding sites (Ehrnebo et al., 1971; Windorfer et al., 1974). Other age-related physiological changes, such as differences in organ perfusion, regional blood flow, and permeability of cell membranes, can also dramatically influence drug binding and distribution.

### Drug metabolism

Compared to older children and adults, neonates and infants exhibit distinct developmental immaturity of many phase I (oxidation; Hines and McCarver, 2002) and phase II (conjugation) drug-metabolizing enzymes (McCarver and Hines, 2002; Tateishi et al., 1997), which can contribute to observed drug toxicities in this age group (Weiss et al., 1960). During postnatal development, distinct patterns of change are observed in the isoform-specific expression

and activity of phase I enzymes, such as the cytochrome P450 family of drug-metabolizing enzymes:

- ♦ The activity of CYP2E1 surges within hours after birth (Vieira et al., 1996).
- ♦ This is immediately followed by the detection of CYP2D6 (Treluyer et al., 1991).
- ♦ By the first week of life, the expression of CYP3A4 (Lacroix et al., 1997) and CYP2C (CYP2C9 and CYP2C19; Treluyer et al., 1997) become detectable.
- ♦ By 1 to 3 months of life, CYP1A2 begins to appear (Sonnier and Cresteil, 1998).

The cytochrome P450 superfamily of enzymes catalyses the oxidation of opioids, converting the parent opioid to a more polar metabolite to facilitate its excretion. Of importance in opioid metabolism are CYP3A4 and CYP2D6. Relatively low levels of P450s are expressed in the foetal liver; the level of CYP2D6 expression reaches only 3% to 5% of adult expression in the third trimester (Ladona et al., 1991). However, expression and activity level of CYP2D6 approaches 95% of adult capacity by 2 weeks of life (Blake et al., 2007). In comparison, the expression of CYP3A4/5 begins to increase at 1 week of life reaching 30% of adult levels by the age of 1 month.

Although the ontogeny of phase II drug-metabolizing enzymes is less well established than phase I drug-metabolizing enzymes, available data suggests that specific isoforms of uridine diphosphate (UDP)-glucuronosyltransferase (UGT) display distinct patterns of maturation, which can markedly affect the pharmacokinetics of drugs (Barrett et al., 1996):

- ♦ The expression and activity of the isoforms UGT1A6 and UGT1A9, are lower in neonates and infants, and the glucuronidation of acetaminophen by UGT1A6 and, to a lesser extent, UGT1A9, is markedly decreased relative to adolescents and adults (Miller et al., 1976)
- ♦ The isoform UGT2B7 can be detected from 24 weeks of gestational age, and glucuronidation of morphine can occur in premature infants (Barrett et al., 1996). As the expression and activity of UGT2B7 markedly increases between 27 and 40 weeks postconceptional age, increases in morphine dose are necessary to maintain therapeutic plasma levels of morphine (Scott et al., 1999).

Glucuronidation plays an important role in the metabolism of many opioids and their metabolites, as the enzyme, uridine 5-diphosphoglucuronosyltransferase, attaches glucuronic acid onto a functional group on the parent opioid to form a highly polar metabolite, which is then eliminated by the kidneys. For example, codeine is converted into codeine-6-glucuronide via UGT2B7. Although the ontogeny of UGT expression is still incompletely understood, it is known that at 15 weeks of gestational age, glucuronidation activity is present. Immediately after birth, UGT activity increases to approximately 10% of adult levels and by 3 to 6 months of age, neonatal activity level of UGT reaches full adult capacity (Pacifci et al., 1982).

Glucuronidation of acetaminophen to produce its toxic metabolite, *N*-acetyl-*p*-benzoquinone-imine (NAPQI), is capable of depleting hepatic glutathione and results in hepatotoxicity (Rumore and Blaiklock, 1992). In contrast to sulphation processes, which are more developed in young children, glucuronidation activity increases with age explaining less hepatotoxicity observed

in children under 6 years of age even when acetaminophen plasma levels are within the range that is toxic at older ages (Rumore and Blaiklock, 1992).

### Elimination of drugs

Beginning at 9 weeks of age, there is a developmental increase in the glomerular filtration rate, a process that is dependent on normal nephrogenesis but is complete by 36 weeks of gestation, and then influenced by postnatal changes in renal and intrarenal blood flow (Robillard et al., 1988). During the first 2 weeks of life, there is a rapid and marked increase in the glomerular filtration rate, which reaches its peak adult values by 8 to 12 months of age (Arant, 1978; van den Anker et al., 1995). Correspondingly, delayed maturation of tubular secretion is observed following birth; however, it reaches adult capacity by the first year of life (Arant, 1978).

As developmental differences in the maturation of renal function can significantly influence the plasma clearance of drugs extensively eliminated by the kidneys (e.g. ceftazidime and famotidine; James et al., 1998), consideration of the ontogeny of renal function and age-appropriate dosing regimens for infants is necessary to avoid potential toxicity.

### Developmental paediatric pharmacodynamics

It is well-established that physiological development plays an important role in the mechanism of action of, and the response to, a drug. However, the effect of ontogeny on the interactions between a drug within the human body and the consequence of these interactions are still incompletely understood. Certain drugs, such as cyclosporine (Marshall and Kearns, 1999) and warfarin (Takahashi et al., 2000), demonstrate developmental differences in the interaction between a drug and the targeted receptor. Whereas, drugs such as midazolam show a clearer relationship between plasma level and the pharmacological effect of the drug (e.g. sedative effect; Marshall et al., 2000).

Functionally and morphologically, the human brain is immature at birth, which contributes to the variability in opioid-related analgesia and respiratory depression. Moreover, the ontogeny of the BBB, drug metabolizing enzymes, and transporters also alter the pharmacodynamics of opioids in neonates. Opioids must travel across the BBB in order to elicit their therapeutic effect; therefore, the amount of opioid that an infant brain is exposed to is in part dependent on the maturity of the BBB. For example, neonates are more sensitive to the respiratory effects of morphine and meperidine compared to older children and adults (Way et al., 1965), and the greater permeability of neonatal brain to opioids (Koren et al., 1985) is one contributing factor. Additionally, human newborns display age-related differences in morphine requirement, and full-term neonates aged 7 days or younger require significantly less morphine to achieve an analgesic effect compared to older children (Bouwmeester et al., 2003; see also Hathway, Chapter 44; Strassels, Chapter 45, this volume).

Low expression and function of P-glycoprotein (P-gp), an efflux transporter, in neonates also contributes to heightened central nervous system (CNS) exposure to morphine. The localization of P-gp along the luminal plasma membrane of the brain capillary endothelium is important, as these transporters efflux xenobiotics to prevent entry and accumulation of neurotoxins or drugs in the brain

(de Vries et al., 2007; Fellner et al., 2002). Although limited data is available regarding the developmental differences in the expression the P-gp transporter, it is known that neonates express P-gp as early as 22 weeks of gestational age, however, at relatively low levels compared to that of adults (Daood et al., 2008). Postmortem analysis of CNS tissue obtained from neonates at 23 to 42 weeks gestational age revealed significantly lower expression levels, but with a similar pattern of P-gp localization to that of adults (Tsai et al., 2002). As such, it is probable that delayed expression and function of P-gp may contribute to a heightened and sustained CNS exposure to morphine (Bouwmeester et al., 2004). Further studies examining the contribution of the ontogeny of P-gp in the analgesic effect of opioids, such as morphine, in neonates are required to fully understand the impact of age-related differences in opioid response.

## Developmental paediatric pharmacogenomics and pharmacogenetics

There are a multitude of genetic factors that can influence the disposition and action of a drug, and these interindividual differences can also elicit very different clinical responses to the same dose of a drug. In addition to physiological developmental differences, genetic polymorphisms in drug metabolizing enzymes and drug transporters also significantly influence the pharmacokinetic and pharmacodynamic responses to certain drugs, such as opioids.

### Polymorphisms in drug metabolizing enzymes

Codeine is an alkaloid of the opium poppy *Papaver somniferum* and its analgesic effects are derived from metabolic conversion to morphine by demethylase activity (International Narcotic Control Board, United Nations: Narcotic Drug, Estimated World Requirements for 2013- Statistics for 2011 and Chen Z.R, Somogyi A.A, Reynolds .G, Bochner .F, 1991). As codeine is considered a 'weak' opioid, it is understood that use was associated with a low incidence of adverse events when compared to 'stronger' opioids. As a result, codeine had been the most commonly prescribed opioid for treatment of mild-to-moderate pain in children (Conroy and Peden, 2001; de Lima et al., 1996). Codeine is available in an oral elixir form for oral administration to infants and young children, and is often used in combination with acetaminophen in a 10:1 ratio of acetaminophen (120 mg/5 ml) to codeine (12 mg/5 ml) (Reisine and Pasternak, 1996). Recent reports have recognized that genetic factors play a major role in the disposition and analgesic effect of codeine (Madadi and Koren, 2008; Madadi et al., 2009), as the primary enzyme cytochrome P450 2D6 (CYP2D6) that O-demethylates codeine to morphine is highly polymorphic (Madadi and Koren, 2008; Olkkola et al., 1995; Yaster and Deshpande, 1988). Functional polymorphisms in genes encoding for metabolic enzymes may lead to altered drug response with either a diminished, excessive, or absent metabolism. The enzymatic activity of CYP2D6 is determined by measuring the urinary metabolic ratio, which is the amount of unchanged drug in urine/amount of O-demethylated metabolite in urine, in comparison with a specified known probe substrate, such as dextromethorphan or desbriquoine. Four phenotypic classifications have been established: poor metabolizers (PM), intermediate (IM) or extensive metabolizers (EM) and ultrarapid metabolizers (UM) (Ito et al., 2010). Genetically, PM exhibit non-functional homozygotes CYP2D6 alleles, IM displays one functional allele and one decrease or null function allele, EM have two functional alleles and UM possess more

than two functional alleles (Ito et al., 2010). In relation to codeine analgesia, metabolism of codeine by CYP2D6 to the active metabolite, morphine, is necessary to achieve an analgesic effect. Therefore, phenotypes of clinical significance are:

- ♦ PM which are associated with therapeutic failure, as deletion or inactive variants of CYP2D6 results in reduced formation of morphine and lack of analgesia. Approximately 5% to 10% of Caucasians are phenotypically classified as PM and thus, are unable to make the conversion of codeine to morphine and they fail to elicit analgesic effects with codeine (Caraco et al., 1999; Madadi and Koren, 2008; Madadi et al., 2009; Sistonen et al., 2007).
- ♦ UM which are associated with severe opioid intoxication, as individuals carrying more than two functional CYP2D6 alleles may produce an excess amount of morphine from codeine (Ciszkowski et al., 2009). Approximately 1% to 2% of Caucasians are classified into the UM phenotype and therefore, these individuals very rapidly and readily convert codeine to morphine resulting in approximately 50% higher plasma concentrations of morphine corresponding to severe opioid intoxication, which may result in a high incidence of CNS depression (Dalen et al., 1997; Kirchheiner et al., 2007; Madadi and Koren, 2008).

In conjunction with genetic polymorphisms in the CYP2D6 gene, ontogeny further contributes to the interindividual variability in CYP2D6 activity. Some studies have demonstrated very low levels of CYP2D6 expression in foetal liver, where only 3% to 5% of adult expression of CYP2D6 is present during the third trimester with a significant increase following the first week of life (Blake et al., 2007; Ladona et al., 1991; Neville et al., 2011). Furthermore, *in vitro* data of CYP2D6 ontogeny demonstrates that CYP2D6 protein expression and activity remain constant after 1 week of life up to 18 years (Neville et al., 2011; Stevens et al., 2008) and that the contribution of CYP2D6 phenotypes in children approaches adult levels at 10 years of age (Stevens et al., 2008). However, significant interindividual variability in CYP2D6 activity is observed during the first year of life (Blake et al., 2007) suggesting that both genetic variation in CYP2D6 expression and activity and developmental factors involving CYP2D6 maturity play important roles in the metabolism of drugs, such as codeine.

Of concern, very few studies have investigated the effects of phenotype, genotype, and adverse events associated with codeine use for infant pain (Williams et al., 2002, 2004). Furthermore, despite several guidelines suggesting a paediatric therapeutic safe dose of less than 2 mg/kg, a threshold that is unlikely to result in adverse drug reactions (ADRs; American Academy of Pediatrics, 1997), there have been reports of severe and life-threatening ADRs associated with the use of codeine at the recommended dose of less than 2 mg/kg in infants and children (Meyer and Tobias, 2005; Sachdeva and Stadnyk, 2005; von Muhlendahl et al., 1976). As such, it is evident that genetic variations, in addition to developmental factors, may amplify the risk of ADRs associated with codeine use in infants and young children and therefore, caution should be taken when prescribing codeine.

### Polymorphisms in opioid transporters

The P-gp transporter, which is encoded by the *ATP-binding cassette B1 (ABCB1)* gene, is expressed in the BBB at the luminal membrane of the brain endothelial cells where it effluxes opioids from the brain to the blood (Xie et al., 1999). P-gp is a major determinant of opioid bioavailability in the CNS, as it is capable of limiting entry

of opioids into the brain (Wandel et al., 2002). Therefore, functional polymorphisms in *ABCB1* may affect opioid disposition into the CNS (Kharasch et al., 2003; Lee et al., 2005; Xie et al., 1999; Zwisler et al., 2010). There have been approximately 35 single nucleotide polymorphisms identified in the coding region of the *ABCB1* gene and it has been suggested that, of these, homozygous 3435T/T carriers undergoing chronic oral morphine exposure may experience greater pain relief than homozygous wild-type 3435C/C (Campa et al., 2008); however, the impact of this variant on P-gp expression in the brain remains unknown.

## Analgesic therapy for paediatric patients

Most pain medications, which include peripheral (e.g. non-steroidal anti-inflammatory drugs (NSAIDs)) and centrally (e.g. morphine and related opioid compounds) acting analgesics, are metabolized by several hepatic enzyme systems, including sulphation, glucuronidation, oxidation, and cytochrome P450 subtypes (Tateishi et al., 1997). However, delayed functional maturation of these enzyme systems in neonates and infants significantly influences the pharmacokinetic properties of these agents with additional age-dependent changes in pharmacodynamic responses to analgesic drugs. The pharmacology of specific drug therapies are covered in more detail in other chapters, but are briefly mentioned here. Acetaminophen and NSAIDs, frequently used to treat mild to moderate pain, have antipyretic effects in infants and young children, and NSAIDs also have anti-inflammatory effects (Brooks and Day, 1991; Maunukela and Olkkola, 1993; Savvas and Brooks, 1991). With the exception of the neonatal period, the pharmacokinetics and pharmacodynamics of NSAIDs in young children are similar to adults (Berde and Sethna, 2002; Mak et al., 2011) and although there is the potential for gastrointestinal and renal toxicities, the incidence in infants and older children is less frequent than observed in adults (Szer et al., 1991; see Anderson, Chapter 43, this volume).

Morphine is the most commonly used intravenous opioid in neonates, infants, and children, as it provides potent analgesia (Anand et al., 2008), but age-related differences in both pharmacokinetic and pharmacodynamic responses during development pose challenges for selection of an appropriate dose (Pasternak et al., 1980). As sensitivity to morphine's CNS effects is increased in neonates (Koren et al., 1993; Reisine and Pasternak, 1996), a lower initial dose of morphine is recommended (Olkkola et al., 1995), which is then titrated against individual response. In addition, the elimination half-life of morphine is more than twice as long as that observed in adults due to the immaturity of neonate's hepatic enzyme system (McRorie et al., 1992). Morphine clearance increases in accordance with the maturation of the glomerular filtration rate (Bouwmeester et al., 2004) and by 1 year of age, the ratio of plasma to cerebral spinal fluid morphine concentration is comparable to that of adults (Hain et al., 1999) (see also Hathway, Chapter 44; Strassels, Chapter 45, this volume).

## Conclusion

Many challenges arise when managing pain in paediatric patients, as pain is a complicated subjective experience and the physiological development of neonates, infants, and children has significant impact on the pharmacokinetic and pharmacodynamics profile

of many analgesic agents. Although there has been significant progress, ongoing investigation and research is required to achieve a thorough understanding of the impact of developmental changes in drug disposition, metabolism and action, to enhance safe and effective pharmacological management of pain in neonates, infants and children.

## CHAPTER 43

# The non-steroidal anti-inflammatory drugs and acetaminophen

Brian J. Anderson

### Summary

The non-steroidal anti-inflammatory drugs (NSAIDs) and acetaminophen (N-acetyl-p-aminophenol, APAP) are the commonest analgesic drugs used in childhood. Although both drugs act through inhibition of prostaglandin H<sub>2</sub> synthetase (PGHS), acetaminophen lacks the anti-inflammatory effects of the NSAIDs. Neonatal acetaminophen hepatic clearance is reduced in premature neonates (5–10% adult rates) and increases to 30% adult rates in neonates born at term; adult rates (approximately 16–20 L/h/70 kg) are reached within the first year of life. NSAID clearance maturation, mostly through cytochrome P450 mixed oxidases, is more rapid. Concentration–response relationships suggest a maximum pain reduction of 5 or 6 on a 10-point scale for both drugs. Combination therapy does not increase this maximum effect but does prolong duration of analgesia. While both drugs have good safety profiles, dosing of both drug groups is tempered by concerns about toxicity. Acetaminophen hepatotoxicity is associated with single doses (>250 mg/kg in preschool children, >150 mg/kg in adults) and therapy duration longer than 3 to 5 days (>90 mg/kg/day). The most common minor adverse events in NSAID recipients are nausea, dizziness, and headache. More concerning is the potential of NSAIDs to cause gastrointestinal irritation, blood clotting disorders, renal impairment, neutrophil dysfunction, and bronchoconstriction. These adverse effects are uncommon provided care is taken with drug dose, duration of therapy, and recognition of contraindications.

### Acetaminophen

#### Mechanism of action

Acetaminophen (N-acetyl-p-aminophenol, APAP, paracetamol) has been used in clinical practice for more than 100 years and is the most commonly prescribed paediatric medicine. Acetanilid, the parent compound of acetaminophen, was introduced in 1886. Toxicity-related problems with acetanilid led to the introduction of acetaminophen in 1893. The popularity of acetaminophen over the non-steroidal anti-inflammatory drugs (NSAIDs) ascended after

the reported association between Reye's syndrome and aspirin in the 1980s (Committee on Infectious Disease, 1982). Acetaminophen is widely used in the management of pain and fever, but is lacking anti-inflammatory effects.

Debate exists about the site of action. Prostaglandin H<sub>2</sub> synthetase (PGHS) is the enzyme responsible for metabolism of arachidonic acid to the unstable prostaglandin H<sub>2</sub>. The two major forms of this enzyme are the constitutive PGHS-1 and the inducible PGHS-2. PGHS is comprised of two sites; a cyclo-oxygenase (COX) site and a peroxidase (POX) site (Figure 43.1). The conversion of arachidonic acid to prostaglandin G<sub>2</sub> is dependent on a tyrosine-385 radical at the COX site. Acetaminophen acts as a reducing cosubstrate on the POX site and lessens the amount of tyrosine-385 radical at the COX site. Alternatively, acetaminophen effects may be mediated by an active metabolite (p-aminophenol). P-aminophenol is conjugated with arachidonic acid by fatty acid amide hydrolase to form AM404. AM404 exerts effect through cannabinoid receptors (Anderson, 2008).

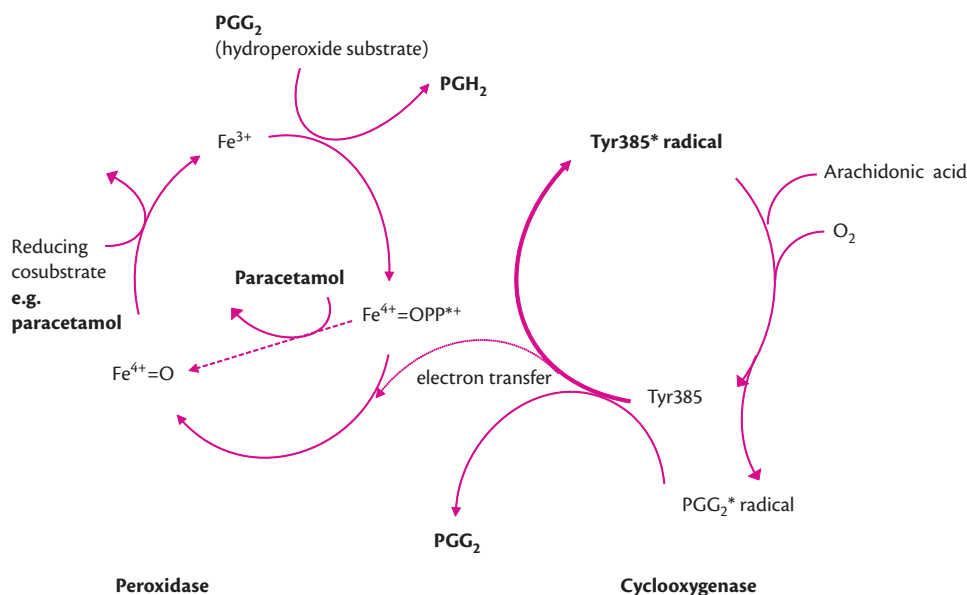

### Pharmacodynamics

The relation between drug concentration and response may be described by the Hill equation or E<sub>max</sub> model:

$$Effect = E_0 + \frac{(E_{max} \cdot Ce^N)}{(EC_{50}^N + Ce^N)} \quad \text{Equation 43.1}$$

where  $E_0$  is the baseline response,  $E_{max}$  is the maximum effect change,  $Ce$  is the concentration in the effect compartment,  $EC_{50}$  is the concentration producing 50%  $E_{max}$  and  $N$  is the Hill coefficient defining the steepness of the concentration–response curve (Figure 43.2). Efficacy is the maximum response on a dose or concentration–response curve.

A delay often exists between plasma and effect site concentration. A single first-order parameter ( $T_{1/2keo}$ ) describes the equilibration half-time between plasma and effect site. The concentration in the effect compartment is used to describe the concentration–effect relationship.

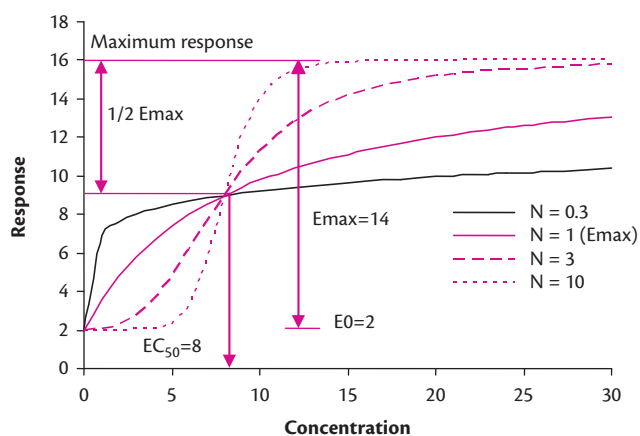

**Figure 43.1** Prostaglandin  $H_2$  synthetase (PGHS) is the enzyme responsible for metabolism of arachidonic acid to the unstable prostaglandin  $H_2$ . Formation of tyrosine-385 radical (Tyr385\*) at the COX site is dependent on the reduction of a ferrylprotoporphyrin IX radical cation ( $Fe^{4+} = OPP^{+}$ ) at the POX site. Acetaminophen is a reducing cosubstrate that partially reduces  $Fe^{4+} = OPP^{+}$ , decreasing the amount available for regeneration of Tyr385\*. Reproduced from Brian J. Anderson, Paracetamol (Acetaminophen): mechanisms of action, *Paediatric Anaesthesia*, Volume 18, Issue 10, pp. 915–921, Copyright © 2008 The Author, by permission of John Wiley & Sons, Inc., <http://onlinelibrary.wiley.com/journal/10.1111/%28ISSN%291460-9592>.

## Analgesia

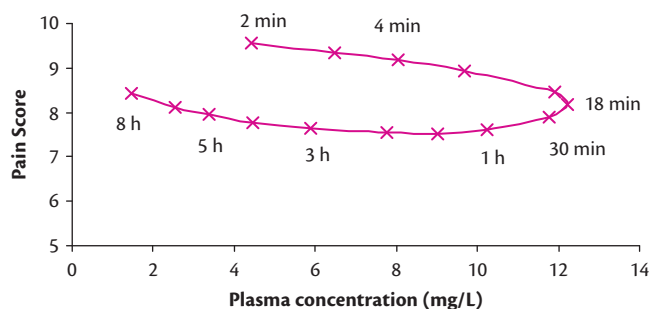

Acetaminophen is an effective analgesic drug. Thirty seven per cent of patients (>13 years of age) given an intravenous (IV) acetaminophen formulation for postoperative pain experienced at least 50% pain relief over 4 h compared with 16% receiving placebo (number needed to treat (NNT) 4.0, 95% confidence interval (CI) 3.5–4.8; Inomata et al., 2003). Increased analgesia has been reported with increasing plasma concentration until a maximum effect (e.g.  $E_{max}$  5.17/10; visual analogue pain score 0–10 after paediatric tonsillectomy). However, the analgesic effect of acetaminophen is not directly related to plasma concentration. Further time is required for the drug to move from the plasma into the effect site. There are time delays of approximately 1 h between peak concentration and peak effect (Figure 43.3); the equilibration half-time ( $T_{1/2keo}$ ) was 53 min (Figure 43.4). A target effect compartment concentration of 10 mg/L is associated with a pain reduction of 2.6/10 (Anderson et al., 2001). Pain fluctuations, pain type, and placebo effects complicate interpretation of clinical studies.

Attempts to unravel these time relationships with studies using oral or rectal acetaminophen are difficult because there are further time delays associated with absorption from the gastrointestinal (GI) tract into the blood. The use of an IV acetaminophen formulation allows greater dosing accuracy, less pharmacokinetic variability attributable to absorption, and more rapid speed of effect onset (Gibb and Anderson, 2008). Infusions over 15 min of IV acetaminophen 15 mg/kg following inguinal hernia repair in children resulted in a steep reduction in pain between 15 and 30 min (Murat et al., 2005), consistent with a delay achieving effect site concentrations in the brain. Two European Centres have published dosing guidelines in neonates (Allegraert et al., 2007; Bartocci and Lundeborg, 2007). These regimens attempt to achieve a steady-state target concentration of 10 mg/L.

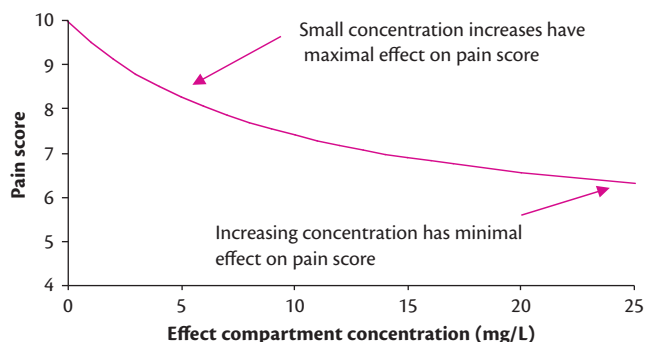

Acetaminophen is commonly used to supplement postoperative analgesia from morphine infusion, but this usually only reduces morphine consumption by 10% to 20% and is probably insufficient to decrease morphine-related adverse effects (Maund et al., 2011).

**Figure 43.2** The  $E_{max}$  model is commonly used to describe the relationship between drug response and concentration. Changing the Hill coefficient dramatically alters the shape of the curve.

**Figure 43.3** The relationship between the plasma concentration and analgesic effect demonstrates clockwise hysteresis. The equilibration half-time ( $T_{1/2keo}$ ) of the analgesic effect compartment was 53 min. Reproduced with permission from I. A. Gibb and B. J. ## Pharmacokinetics

### Oral absorption

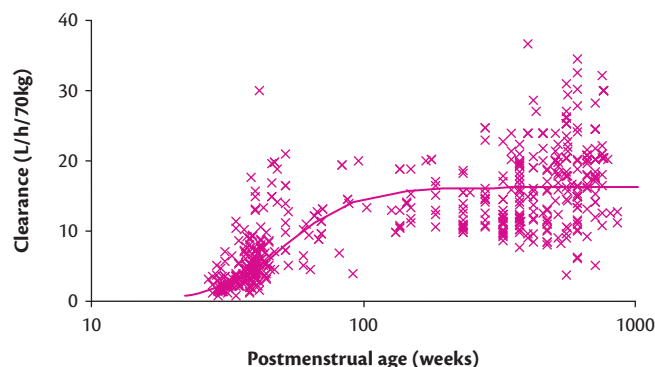

Acetaminophen has low first-pass metabolism, and the hepatic extraction ratio is 0.11 to 0.37. Acetaminophen is rapidly absorbed from the duodenum to the systemic circulation. There is usually a short interval before the drug enters the duodenum from the stomach (5 min) and then absorption is rapid; absorption half-life is 2 to 5 min (Anderson et al., 2000; Brown et al., 1992). Absorption in children under the age of 3 months is delayed because absorption depends on gastric emptying, and gastric emptying is slow and erratic in the neonate. Normal adult rates may not be reached until 6 to 8 months.

### Rectal absorption

Rectal acetaminophen is widely used in children presenting for surgical procedures because of GI dysfunction or preoperative fasting guidelines that disallow food or fluids up to 6 h before surgery. It is also preferable in children with nausea and vomiting. The relative bioavailability of rectal compared with oral acetaminophen formulations ranges from 0.24 to 0.98. Absorption through the rectal route is slow and erratic (absorption half-life 0.65–1.34 h). The absorption half-life for rectal formulations is prolonged in infants younger than 3 months (1.51 times greater) compared to values in older children (Anderson et al., 2002).

### Clearance

Acetaminophen is metabolized predominantly by uridine diphospho-glucuronosyltransferases (UGT1A6). This enzyme is immature in neonates, although some acetaminophen can be metabolized by sulphate conjugation, which is mature in term neonates. Maturation of clearance is completed in within the first few years of life and reflects the maturation of the UGT1A6 isoenzyme (Miyagi and Collier, 2011). Clearance increases from 27 weeks postmenstrual age (1.87 L/h/70 kg) to reach 84% of the mature value (c.16–20 L/h/70 kg) by 1 year of age (Figure 43.5) (Anderson et al., 2002, 2005). Clearance through sulphate conjugation is saturable and dependent on substrate availability (Reith et al., 2009). It is also possible that APAP may induce glucuronosyltransferase, leading to increased clearance after repeat therapeutic dosing (Gelotte et al., 2007). Total body clearance is first order after very high doses

**Figure 43.5** Clearance changes with age. Individual predicted clearances, standardized to a 70 kg person, from the NONMEM program's post hoc step are plotted against age. The thin line demonstrates the predicted non-linear relationship between clearance and age. Reproduced from Brian J. Anderson and Karel Allegaert, Intravenous neonatal acetaminophen dosing: the magic of ten days, *Paediatric Anaesthesia*, Volume 19, Issue 4, pp. 289–295, Copyright © 2009 The Authors, by permission of John Wiley & Sons, Inc., <http://onlinelibrary.wiley.com/journal/10.1111/%28ISSN%291460-9592>.

(20 g/m<sup>2</sup>) when used to augment alkylating drugs for melanoma treatment (Wolchok et al., 2003).

### Volume of distribution

The volume of distribution in children is similar to those reported in adults (56–70 L; Prescott, 1996). Peripheral volume of distribution decreased from 27 weeks postmenstrual age (45.0 L/70 kg) to reach 110% of its mature value by 6 months of age (Figure 43.6) (Anderson et al., 2005), reflecting neonatal body composition and the rapid changes in body water distribution in early life.

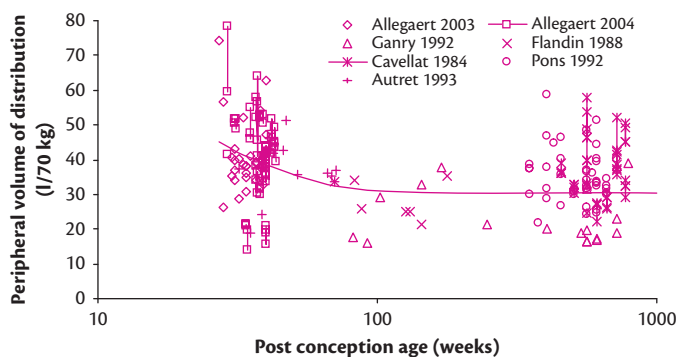

### Disease states

The effects of altered physiology such as fever, anaesthesia, or mildly impaired hepatic dysfunction on pharmacokinetic parameters have received little attention, but appear to have minimal impact in children. Similarly, chronic conditions such as diabetes and renal failure have minimal impact on pharmacokinetics. Clearance is reduced in disease states where we might expect reduced hepatic function; hypothyroidism, congestive heart failure, acute viral hepatitis. The impact of obesity is unknown. Bilirubin is also cleared by a glucuronosyltransferase (UGT1A1); increased unconjugated bilirubin concentration in neonates is an indicator of reduced hepatic function and consequently reduced clearance. However size (predicted by weight) is the major covariate of clearance variance in neonates (Allegaert et al., 2011).

### Toxicity

#### Chronic use of acetaminophen

Hepatotoxicity is the principal adverse effect. The toxic metabolite of acetaminophen, *N*-acetyl-*p*-benzoquinone imine (NAPQI), is formed by the CYP2E1. Hepatotoxicity is dependent on the balance between the rate of NAPQI formation, capacity of the safe elimination pathways of sulphate and glucuronide production, and the initial content and maximal rate of synthesis of hepatic glutathione that mops up NAPQI. NAPQI binds to intracellular hepatic macromolecules to produce cell necrosis and damage. During hepatocyte lysis APAP-protein adducts are released into plasma and these can be used as specific biomarkers of APAP toxicity in patients with acute liver injury (Bond, 2009; James et al., 2009).

**Figure 43.6** Peripheral volume of distribution changes with age. Individual predicted volumes, standardized to a 70 kg person, against age. The solid line demonstrates the non-linear relationship between volume of distribution and age. Those children given multiple doses have volume of distribution estimates linked by a fine line to demonstrate between occasion variability. Reproduced from Brian J. Anderson et al., Paediatric intravenous acetaminophen (propacetamol) pharmacokinetics: a population analysis. *Paediatric Anaesthesia*, Volume 15, Issue 4, pp. 282–292, Copyright © 2005 The Authors, by permission of John Wiley & Sons, Inc., <http://onlinelibrary.wiley.com/journal/10.1111/%28ISSN%291460-9592>

Significant hepatic and renal disease, malnutrition, and dehydration may increase the propensity for toxicity. Medications that induce the NAPQI formation (e.g. phenobarbitone, phenytoin, and rifampicin) may also increase the risk of hepatotoxicity. The influence of disease on acetaminophen toxicity is unknown. Hepatotoxicity causing death or requiring liver transplantation has been reported with doses above 75 mg/kg/day in children and 90 mg/kg/day in infants. It is possible that even these traditional regimens may cause hepatotoxicity if used for longer than 2 to 3 days (Kearns et al., 1998).

Hepatic enzyme profiles have been used as a surrogate assessment in neonatal studies. Although no hepatic changes occurred during the treatment periods that extended over a median of 4 days, the value of hepatic changes is debated (Anderson and Allegaert, 2009). It is currently impossible to predict which individuals have an enhanced susceptibility to cellular injury from acetaminophen.

### Single dose of acetaminophen

The Rumack and Matthew (Rumack and Matthew, 1975) acetaminophen toxicity nomogram is widely used to guide management of acetaminophen overdose in adults and children. Acetaminophen concentrations of more than 300 mg/L at 4 h were always associated with severe hepatic lesions, but none were observed in adults with concentrations less than 150 mg/L. The half-life was less than 4 h in all patients without liver damage.

Clearance, expressed as L/h/kg is greater in children than adults. The 4 h concentration is determined by clearance in preschool children following accidental ingestion of elixir where absorption is rapid. As a consequence, younger children (1–5 years) require larger doses than older children and adults to achieve similar concentrations at 4 h. Children (1–5 years) with reported accidental ingestion of greater than 250 mg/kg (compare to 150 mg/kg in adults) can have serum concentration measured at 2 h after ingestion rather than the 4 h time point recommended in adults (Anderson et al., 1999).

Neonates can produce NAPQI, but CYP2E1 in neonates is immature at birth. This may explain the low occurrence of acetaminophen-

induced hepatotoxicity seen in neonates, despite reports of high serum concentrations in newborn neonates. Neonatal hepatotoxicity has been reported in an ex-term (41-week) neonate who presented encephalopathic at 5 days following 3 days of oral acetaminophen dosing—initially 156 mg/kg/day and then 78 mg/kg/day. The neonate had an unconjugated hyperbilirubinaemia (130  $\mu\text{mol/L}$ ) on admission with marked liver derangement and after receiving N-acetyl cysteine recovered fully over 7 days (Walls et al., 2007).

### Dosing with formulation

Suggested acetaminophen dosing for different age groups is shown in Table 43.1. These dosing regimens achieve a target concentration of 10 mg/L, but may be considered too high as concerns about dose and hepatotoxicity increase. Children seek rapid relief from symptoms, be they pain or fever. In general, the smaller the child, the shorter the  $T_{1/2\text{keo}}$ , but absorption characteristics of enteral acetaminophen in neonates delays analgesia onset. Speed of onset may be shortened by giving a larger initial dose or improving absorption characteristics or changing the formulation (Gibb and Anderson, 2008). Target effect compartment concentrations (and effect) will be reached earlier as dose is increased. The administration of a large initial oral or rectal 'loading' dose will achieve the target concentration speedily, but such dosing may exceed the subsequent daily dose recommendation. Formulation has considerable impact. For example the slow absorption of rectal acetaminophen suppositories means peak concentrations are only reached after several hours. In contrast an IV formulation has rapid onset of analgesia (Figure 43.7).

## Non-steroidal anti-inflammatory drugs

### Mechanism of action

The NSAIDs are a heterogeneous group of compounds that share common antipyretic, analgesic, and anti-inflammatory effects (Table 43.2). Their major action is through inhibition of prostaglandin synthesis. NSAIDs act by reducing prostaglandin biosynthesis through inhibition at the COX site of PGHS (Figure 43.8). The two major forms of this enzyme are the constitutive PGHS-1 and the inducible PGHS-2 (COX-1 and COX-2). This enzyme converts arachidonic acid to cyclic endoperoxides. The prostinoids produced by COX-1 protect the gastric mucosa, regulate renal blood flow, and induce platelet aggregation. NSAID-induced GI toxicity, for example, is generally believed to occur through blockade of COX-1 activity, whereas the anti-inflammatory effects of NSAIDs are thought to occur primarily through inhibition of the inducible isoform, COX-2. Relative COX-1/COX-2 specificity ratios vary from greater than 1 (aspirin, indomethacin, ibuprofen), approximately 1 (diclofenac, naproxen), to less than 1 (celecoxib, etoricoxib).

### Pharmacodynamics

The NSAIDs are commonly used in children for antipyresis and analgesia. The anti-inflammatory properties of the NSAIDs have, in addition, been used in such diverse disorders as juvenile idiopathic arthritis, renal and biliary colic, dysmenorrhoea, Kawasaki disease, and cystic fibrosis. The NSAIDs indomethacin and ibuprofen are also used to treat delayed closure of patent ductus arteriosus in premature neonates.

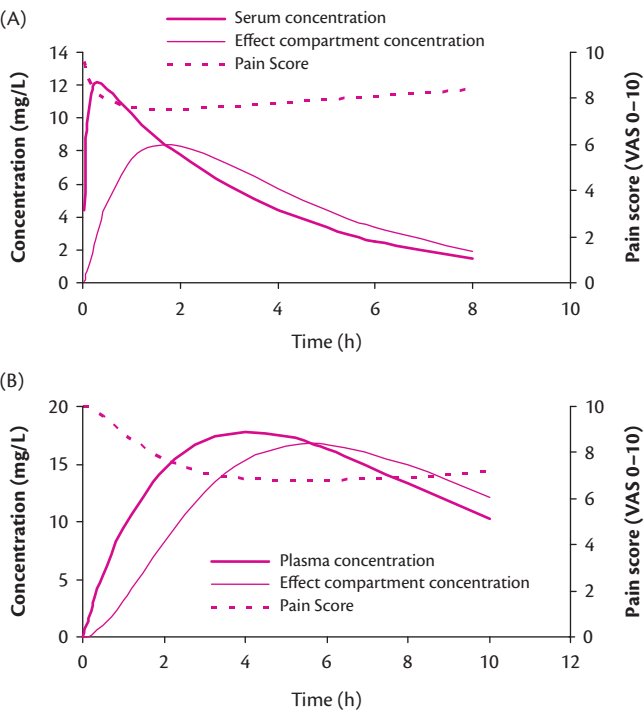

Pain relief attributable to NSAIDs has been compared to pain relief from other analgesics or analgesic modalities (e.g. caudal blockade, acetaminophen, and morphine). Studies comparing

Table 43.1 Suggested acetaminophen dosing

Age	Typical body weight (kg)	Acetaminophen clearance (L/h/kg)	Acetaminophen dose (oral)
Neonate	3.3	0.21	50 mg, 8 h
3 months	6	0.25	90 mg, 6 h
6 months	7.5	0.27	120 mg, 6 h
1 year	10	0.29	120 mg, 4 h
5 years	18	0.25	250 mg, 4 h
8 years	24	0.24	300 mg, 4 h
12 years	38	0.21	375 mg, 4 h
16 years	50	0.3	500 mg, 4 h
Adult	70	0.3	1000 mg, 6 h

The maintenance dose of acetaminophen for a patient is calculated as follows: acetaminophen maintenance dose = acetaminophen clearance × target concentration. Individual clearance values can be predicted from weight and age (Anderson et al., 2002). Most of the age-related changes in clearance are complete by 1 year of age. There are also size-related changes in clearance so that the value per kg continues to decrease as weight increases in children (Anderson and Meakin, 2002; Anderson et al., 1997). Clearance in adults is reported as higher than in children. The doses have been calculated to maintain a target serum acetaminophen concentration of 10 mg/L and a lower target may be preferred because of hepatotoxicity concerns

For patients more than 20% overweight, use ideal body weight. Children prefer elixir to capsules or tablets. It is important to note that elixir formulation is available in different formulation strengths when prescribing the dose by volume. Proprietary cough and cold medications containing acetaminophen are also available. Concurrent use of such medications can result in inadvertent acetaminophen toxicity. The relative bioavailability of rectal formulations is reduced out of the neonatal period and dose can be increased by 30%. Dose is reduced in premature neonates (e.g. 24 and 45 mg/kg/d at 30 and 34 weeks postmenstrual age, respectively).

**Figure 43.7** (A) The temporal relationships for plasma concentration, effect compartment concentration and analgesic effect after 12.5 mg/kg acetaminophen elixir in a child. The absorption half-time used was 4.5 min. (B) The temporal relationships for plasma concentration, effect compartment concentration and analgesic effect after 20 mg/kg acetaminophen suppository in an adult. Maximum effect lags an hour behind the 4 h peak concentration. Reproduced with permission from I. A. Gibb and B. J. Anderson, Paracetamol (acetaminophen) pharmacodynamics: interpreting the plasma concentration, *Archives of Disease in Childhood*, Volume 93, Issue 3, pp. 241–247, Copyright © 2008 BMJ Publishing Group Ltd and Royal College of Paediatrics and Child Health, <http://adc.bmj.com/>.

ketorolac (0.75–1 g/kg) to morphine (0.1 mg/kg) for analgesia after paediatric tonsillectomy, strabismus surgery, or general surgery have demonstrated similar degrees of analgesia with reduced emesis with some increased bleeding in children given ketorolac. Diclofenac and ketorolac reduce morphine use by up to 40% in children after a surgical insult.

Conflicting reports plague the literature as to whether NSAIDs or acetaminophen display greater analgesic effect when given alone. An early meta-analysis comparing single doses of acetaminophen 7 to 15 mg/kg with ibuprofen 4 to 10 mg/kg found similar analgesic effect in children (Perrott et al., 2004). A more recent meta-analysis identified 54 studies directly comparing the analgesic effect of acetaminophen with ibuprofen (Pierce and Voss, 2010). The authors concluded that ibuprofen is at least as effective as, if not more so than, acetaminophen in both adults and children. These comparisons are difficult to interpret because of differences in pain insult, timing of response, duration and nature of pain scores, patient ages, doses administered, and formulations used (Anderson, 2004).

NSAIDs appear to be equally effective at commonly used doses (Davies and Skjodt, 2000). It has been suggested (Maunukela and Olkkola, 2003) that 1 mg/kg of rectal diclofenac = 10 mg/kg of oral ibuprofen = 40 mg/kg of rectal acetaminophen = 5 mg/kg of IV ketoprofen = 0.5 mg/kg of IV ketorolac. A single dose of ibuprofen 400 mg had a NNT of 2.5 for at least 50% pain relief compared with placebo (Collins et al., 2002; Kopacz and Bernards, 2001). This means that two of every five adults with pain of moderate to severe intensity will experience at least 50% pain relief with ibuprofen, which they would not have had with placebo. The equivalent NNTs for ibuprofen 200 and 600 mg were 3.3 and 2.4, respectively, and those for diclofenac 25, 50, and 100 mg were 2.6, 2.3, and 1.8, respectively (Table 43.3).

NSAID concentration–response relationships are rare in children, but have been described for adults. Data from adults given

**Figure 43.8** The conversion of arachidonic acid to  $PGG_2$ , the precursor of the prostaglandins is controlled by prostaglandin  $H_2$  synthetase (PGHS). PGHS comprises of two sites; a cyclooxygenase (COX) site and a peroxidase (POX) site

ibuprofen after dental extraction suggest a similar  $E_{max}$  to that described for acetaminophen (1.54 of a scale 0–3; Li et al., 2012). The equilibration half-time ( $T_{1/2keo}$ ) of 28 min was less than the 53 min reported for acetaminophen (Anderson et al., 2001). In addition, the slope of the concentration–response curve was steeper than that for acetaminophen (Hill = 2 for ibuprofen, Hill = 1 for acetaminophen) indicating a more rapid onset of analgesia. Data from adult patients given ketorolac for postoperative pain relief after orthopaedic surgery revealed an  $E_{max}$  of 8.5/10 (VAS 0–10) and  $T_{1/2keo}$  24 min (Mandema and Stanski, 1996).

Interpretation of analgesia is also complicated by active metabolites. Naproxenolone is an active metabolite of naproxen (Ingelmo and Fumagalli, 2005). Diclofenac's 4'-hydroxyl metabolite has 30% of the anti-inflammatory and antipyretic activity of the parent

compound. Approximately 20% of the parent drug is processed to this metabolite. Despite the impact of this metabolite, there are reasonable data to support the contention that diclofenac 50 mg is as effective as diclofenac 100 mg in adults (McQuay and Moore, 1998; Wong and Baker, 1988). Little or no information on developmental differences in arachidonic acid release, prostaglandin formation, or COX-2 expression is available for the paediatric population. It has been assumed that attaining similar adult exposure to 50 mg in children should give similar effectiveness. This argument has been used to support a single dose of diclofenac 0.3 mg/kg for IV, 0.5 mg/kg for suppositories, and 1 mg/kg for oral diclofenac in children aged 1 to 12 years (Standing et al., 2011).

### Pharmacokinetics

Pharmacokinetic age-related changes and covariate effects are poorly documented for many of the NSAIDs. There are limited data in infants less than 6 months age (Litalien and Jacqz-Aigrain, 2001). NSAID formulations may be administered orally, topically, intraocularly, intra-articularly, intravenously, intramuscularly, and rectally. NSAIDs are rapidly absorbed in the GI tract after oral administration. Time to maximal concentration is generally 1 to 2 h, but depends on formulation and concomitant food intake. Absorption due to the dissolution time of diclofenac tablets is slower than that associated with effervescent or liquid formulations (Standing et al., 2011). An absorption lag time of 1 h has been reported in children given enteric-coated diclofenac tablets (Romsing et al., 2001). The relative bioavailability of oral preparations approaches 1 compared to IV administration. The rate and extent of rectal absorption of NSAIDs such as ibuprofen, diclofenac, flurbiprofen, indomethacin, and nimesulide is generally less than those by oral routes.

The apparent volume of distribution ( $V/F$ ) is small in adults (less than 0.2 L/kg, suggesting minimal tissue binding) but is larger in children; for example, ketorolac  $V/F$  in children 4 to 8 years old is twice that of adults (Forrest et al., 1997; Olkkola and Maunukela, 1991). Premature neonates (22 to 31 weeks gestational age) given IV ibuprofen had a  $V/F$  of 0.62 (SD 0.04) L/kg (Aranda et al., 1997). A dramatic reduction in ibuprofen central volume following closure of the PDA in premature neonates (0.244 versus 0.171 L/kg) is reported (Van Overmeire et al., 2001).

The NSAIDs, as a group, are weakly acidic, lipophilic, and highly protein bound. The bound fraction in children and premature neonates is slightly lower than in adults. The impact of this reduced protein binding is probably minimal with routine dosing because NSAIDs cleared by the liver have a low hepatic extraction ratio and they have a long equilibration time between plasma and effect compartments (Benet and Hoener, 2002). There is relatively little transfer from maternal to fetal blood. Excretion of NSAIDs into breast milk of lactating mothers is low.

NSAIDs undergo extensive phase I and phase II enzyme biotransformation in the liver, with subsequent excretion into urine or bile. Enterohepatic recirculation occurs when a significant amount of an NSAID or its conjugated metabolites are excreted into the bile and then reabsorbed in the distal intestine. Pharmacokinetic parameter estimate variability is large, partly attributable to covariate effects of age, size, and pharmacogenomics. Ibuprofen, for example, is metabolized by the CYP2C9 and CYP2C8 subfamily. It is known that considerable variation exists in the expression of CYP2C activities among individuals, and functional polymorphism of the gene coding for CYP2C9 has been described.

NSAID elimination is all too frequently described only in terms of half-life, which is therefore confounded by volume of distribution. The plasma half-lives of NSAIDs in adults range from 0.25 to greater than 70 h, indicating wide differences in clearance rates. Elimination half-lives are longer in neonates than in children. An elimination half-life of 30.5 h was reported in premature infants receiving ibuprofen within the first 12 h of life (Aranda et al., 1997), in contrast with 1.6 h in infants and children aged 3 months to 10 years (Kelley et al., 1992). Clearance increases from birth; ibuprofen clearance increases from 2.06 ml/h/kg at 22 to 31 weeks postmenstrual age (Aranda et al., 1997), 9.49 ml/h/kg at 28 weeks postmenstrual age (Van Overmeire et al., 2001), to 140 ml/h/kg at 5 years (Scott et al., 1999) (Table 43.4). Clearance (L/h/kg) is generally increased in childhood both for the established NSAIDs and for the newer COX-2 inhibitors. This increased clearance is common for most drugs in childhood. Age-related ketorolac pharmacokinetic parameter estimates after 0.5 mg per kg intravenously are shown in Table 43.5. Elimination clearance, corrected for size using an allometric  $3/4$ -power model (Anderson and Holford, 2008), is similar to adult estimates from 1 year of age. Data from infants under the age of 1 year suggest higher clearance estimates of 1.5 ml/min/kg (Cederholm et al., 1992; Demiraran et al., 2008).

Many NSAIDs are formulated as a racemic mixture where only one isomer is active, but where the other may influence pharmacokinetics (stereoselectivity). Ibuprofen stereoselectivity has been reported in premature neonates (<28 weeks of gestation). R- and S-ibuprofen half-lives were about 10 h and 25.5 h, respectively. The mean clearance of R-ibuprofen (12.7 ml/h) was about 2.5-fold higher than for S-ibuprofen (5.0 ml/h) (Gregoire et al., 2004). Similar data have been reported for ketorolac (Hansen et al., 2001; Kristensen et al., 1998). Single-isomer NSAIDs are appearing for the treatment of acute pain and may have fewer adverse effects than traditional NSAIDs.

Reports of the use of COX-2 selective inhibitors in children are appearing in the literature, but their future use is still uncertain following reports of atherothrombosis in adults. Future benefits may be derived from nitric oxide or hydrogen sulphide releasing NSAIDs

that have increased potency and reduced side effects (Fiorucci and Distrutti, 2011).

## Drug interactions

High protein binding among the NSAIDs has been used to explain drug interactions with oral anticoagulant agents, oral hypoglycaemics, sulphonamides, bilirubin, and other protein-bound drugs. Warfarin administered with phenylbutazone increased plasma warfarin concentrations and prothrombin time in normal volunteers. Phenylbutazone displaces warfarin from its albumin-binding sites *in vitro*, but this observation cannot be extrapolated to an *in vivo* effect. The observed effect is due to changes in drug metabolic clearance and not from changes in protein binding.

The NSAIDs can reduce the antihypertensive effect of angiotensin-converting enzyme inhibitors and  $\beta$ -blockers with possible loss of blood pressure control and can attenuate the natriuretic effect of thiazide diuretics and furosemide. Concurrent administration of probenecid decreases NSAID renal clearance. Lithium and methotrexate concentrations may be increased due to decreased renal clearance. Significant drug interactions have also been demonstrated for aspirin, digoxin, cyclosporine, cholestyramine, and colestipol (Davies and Anderson, 1997).

## Renal failure

Renally excreted NSAIDs such as azapropazone may accumulate in renal failure. Ketoprofen and naproxen are metabolized via the acyl glucuronidation pathway, and also may accumulate in renal failure. Renal impairment is a risk factor for NSAID-induced renal toxicity (Davies and Skjodt, 2000).

## Hepatic disease

Hypoalbuminaemia will alter the volume of distribution of NSAIDs. NSAIDs that are mainly eliminated by hepatic oxidative metabolism may require dose reduction, or should be avoided in the presence of significant liver disease (Davies and Skjodt, 2000).

## Safety issues

The most common adverse events in NSAID recipients are nausea, dizziness, and headache. NSAIDs have potential to cause GI irritation, blood clotting disorders, renal impairment, neutrophil dysfunction, and bronchoconstriction; effects postulated to be related to COX-1/COX-2 ratios, although this concept may be an oversimplification. COX-2, for example, is constitutively expressed in renal tissues of all species. It seems unlikely that these COX-2 inhibitors will offer renal safety benefits over non-selective NSAID therapies. It is reasonable to assume that all NSAIDs, including COX-2-selective inhibitors, share a similar risk for adverse renal effects (Brater et al., 2001).

One other concern is the sudden and profound bradycardia after rapid IV administration of ketorolac. Although the mechanism of this response is unclear, ketorolac should be administered slowly when given intravenously. Most children are asymptomatic after NSAID accidental overdose. Symptoms may comprise tinnitus, diarrhoea, nausea, blurred vision, drowsiness, vomiting, headache, agitation, confusion, rash, and sweating with increasing dose (e.g. >100 mg/kg ibuprofen). Severe overdose (e.g. ibuprofen >400 mg/kg) can be life threatening and present with respiratory depression, cardiovascular compromise, metabolic acidosis, renal failure, and altered neurological state.

## Renal effects

The effect of short-term treatment with NSAIDs on healthy kidneys is negligible. Ibuprofen reduced the glomerular filtration rate by 20% in premature neonates, affecting aminoglycoside clearance, and this effect appears independent of gestational age (Allegaert et al., 2005). Large studies involving ibuprofen (Lesko and Mitchell, 1997, 1999) and ketorolac (Houck et al., 1996) have shown little risk in children (e.g. upper 95% bound was 5.4 per 100 000 ibuprofen-treated children). Similar data are reported in children suffering juvenile rheumatoid arthritis (JIA) given NSAIDs as long-term treatment. However, renal compromise is described in children suffering dehydration, hypovolaemia, hypotension, or pre-existing renal disease. NSAIDs may also potentiate the toxicity of other drugs such as aminoglycosides and ciclosporin.

## Gastrointestinal effects

Adverse GI effects are significant in adults, particularly in those with peptic ulcer disease, *Helicobacter pylori*, or advanced age. The risk of acute GI bleeding in children given short-term ibuprofen was estimated to be 7.2 in 100 000 (95% CI, 2–18 in 100 000) (Lesko and Mitchell, 1995, 1999) and was not different from those children given acetaminophen. Similar data are reported in children given ketorolac for acute pain (Forrest et al., 1997). The incidence of clinically significant gastropathy is comparable to adults in children given NSAIDs for JIA (Dowd et al., 1995; Keenan et al., 1995), but gastroduodenal injury may be very much higher depending on assessment criteria.

## Bone healing

NSAIDs, but not acetaminophen, impair fracture healing in animal models. COX-2 activity plays an important role in bone healing and the use of NSAIDs decreases osteogenic activity that may increase the incidence of non-union after spinal surgery. The effect on osteogenic activity is dose-dependent and reversible. These effects are cause for concern after major orthopaedic surgery (Dodwell et al., 2010), but there was no risk of non-union with NSAID exposure when high-quality studies were assessed.

## Bleeding propensity

The commonly used NSAIDs such as ketorolac, diclofenac, ibuprofen, and ketoprofen have reversible antiplatelet effects, which are attributable to the inhibition of thromboxane synthesis. Bleeding time is usually slightly increased in the perioperative period, but it remains within normal limits in children with normal coagulation systems. A Cochrane review has established that even after tonsillectomy, NSAIDs did not cause any increase in bleeding that required a return to theatre in children (Cardwell et al., 2005). There was significantly less nausea and vomiting with NSAIDs compared to alternative analgesics, suggesting their benefits outweigh their negative aspects.

The use of ketorolac analgesia for tonsillectomy, however, has been associated with increased bleeding. This was attributable to the dose used and whether it is given preoperatively or postoperatively and duration of therapy (Strom et al., 1996). The risk associated with the drug was larger and clinically important when ketorolac was used in

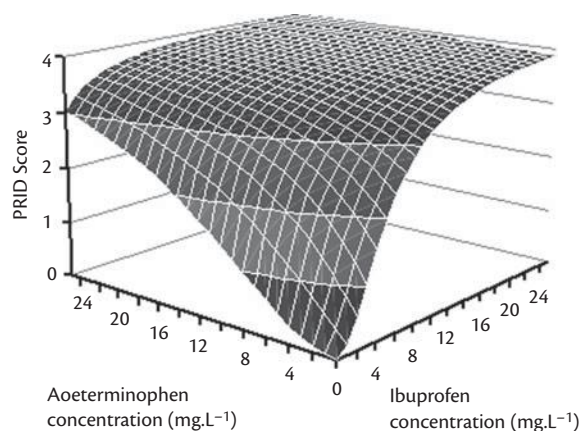

higher doses, in older subjects, and for more than 5 days. It is reasonable to not administer this medication until the end of surgery after haemostasis is achieved. Forrest et al. have suggested an IV dose of ketorolac in children of 0.5 mg/kg, followed either by bolus injections of 1.0 mg/kg every 6 h or an IV infusion of 0.17 mg/kg/h (Forrest et al., 1997). The maximum daily dose is 90 mg, and the maximum duration of treatment is 48 h. The recommended oral dosage is 0.25 mg/kg to a maximum of 1.0 mg/kg/day, with a maximum duration of 7 days.

## Asthma

Aspirin or NSAID exacerbated respiratory disease (ERD) is more a disorder of adults but exacerbations in children and teenagers have been reported. This adverse effect is countered by a beneficial reduction of asthma symptoms where ibuprofen was administered for antipyresis. Benefit is likely seen in younger children with mild episodic asthma and ERD is a concern in one in three teenagers with severe asthma and coexistent nasal disease. COX-2 inhibitors are reported as safe in NSAID-ERD (Palmer, 2005).

## The acetaminophen–NSAID interaction

Acetaminophen and NSAIDs are often given together for the management of pain or fever. They can be safely combined without increases in their associated adverse effect profiles and combination therapy is popular. A review of randomized controlled studies comparing combined acetaminophen and ibuprofen therapy for postoperative pain management identified six studies (Ong et al., 2010). Of these, three were conducted in paediatric populations: oral premedication with acetaminophen and ibuprofen was supported over acetaminophen alone for tonsillectomy pain in children and following tooth extraction; while rectally administered acetaminophen and ibuprofen showed no benefit over acetaminophen alone for pain following adenoidectomy, although a reduction in rescue analgesia was seen in the combination group once home.

**Figure 43.9** Theoretical response surface of effect between acetaminophen and ibuprofen. Concentrations are those in the effect compartment. The concentration response for acetaminophen is plotted on the x–y axis, while that for ibuprofen is on the z–y axis. The ‘surface’ is that plotted between these axes. Reproduced with permission from Jacqueline Hannam and Brian J. Anderson, Explaining the acetaminophen–ibuprofen analgesic interaction using a response surface model, *Paediatric Anaesthesia*, Volume 21, Issue 12, pp. 1234–1240, Copyright © 2011 Blackwell Publishing Ltd, <http://onlinelibrary.wiley.com/journal/10.1111/%28ISSN%291460-9592>.

Disparities between results may stem from differences in the endpoint studied (particularly for assessments of analgesia) and dissimilar dosing regimens, as well as a plethora of other factors relating to study design, conduct and analysis. Dose–response curves published in adults (Mehlisch et al., 2010) for combination acetaminophen–ibuprofen therapy have been investigated for combination therapy response. Pain after dental surgery was measured using pain intensity differences (PRID, 0–8) from 0 to 8 h. Analysis of the response surface area (Figure 43.9) allowed dose interpretation in children (Hannam and Anderson, 2011). Simulation for a 20 kg child showed the addition of acetaminophen to ibuprofen doses of less than 5 mg/kg was effective; acetaminophen had minimal effect when given with ibuprofen at doses greater than 5 mg/kg in the immediate postoperative period. A more sustained analgesic effect was noted at 4 to 8 h after combination dosing (Figure 43.10).

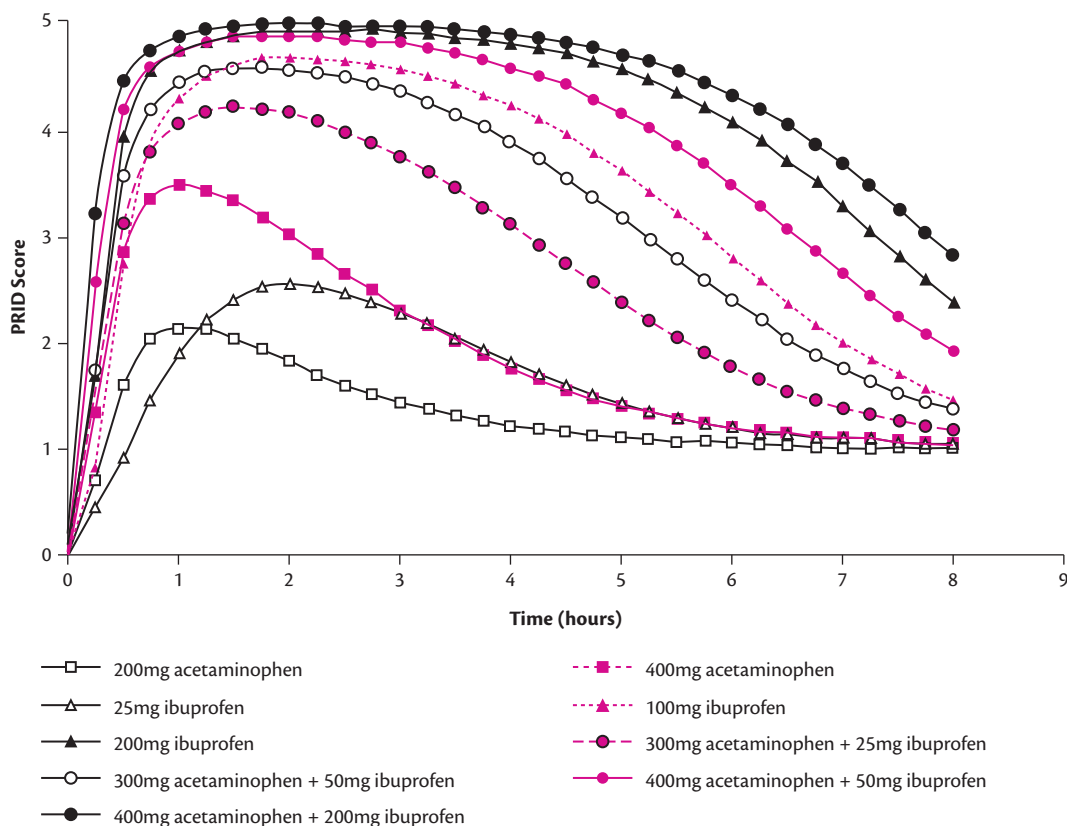

## Hepatotoxicity attributed to the therapeutic administration of acetaminophen

### Case example

A 3-year-old boy suffered a depressed compound right-sided skull fracture with underlying brain contusion. He presented 1 h after injury with apnoea, hypovolaemia, and a Glasgow Coma Score of 6/15. Intubation, ventilation, volume resuscitation, and inotropes were instituted and the child went forward for emergency right fronto-temporal craniotomy and debridement of the fracture site. Postoperatively he remained stable. Prophylactic phenytoin was used for possible seizure activity and intermittent phenobarbital for sedation. Acetaminophen 100 mg/kg/day was administered through the nasogastric tube to control hyperpyrexia. Serum concentrations of acetaminophen were not measured. Serum aspartate aminotransferase (AST) was elevated to 610 IU/L on day 2. On day 3 he developed a metabolic acidosis with a base deficit of 9 mmol/L. There was a dramatic rise in AST (10 000 IU/L) and a moderate increase in gammaglutamyltransferase (GGT 113 IU/L) concentrations. The coagulation profile was disordered (APTT 79, PR 3.3, fibrinogen 1.6g/L).

Abdominal contrast-enhanced computed tomography (CT) revealed a large wedged-shaped area of non-enhancement in the right lobe of the liver with a large volume of free intraperitoneal fluid in the hepatorenal fossa, the right paracolic gutter, and the lesser sac of the pelvis. The lesion was assumed to represent a laceration and was managed conservatively; however, over the subsequent 48 h the child developed fulminant hepatic failure with multiple system organ involvement. Treatment was withdrawn on day 5.

Postmortem liver sections showed coagulative necrosis involving zone 3 which, in some areas, extended into zone 2 of the liver acinus. There was sparing of periportal areas. The portal triads were unremarkable. There was a mild acute inflammatory response associated with the coagulative necrosis. There was no evidence of centrilobular congestion or sinusoidal engorgement. There was no evidence of a laceration in the right lobe.

**Figure 43.10** Simulated PRID scores for a 5-year-old, 20 kg child given single and combination acetaminophen-ibuprofen therapy.

Reproduced with permission from Jacqueline Hannam and Brian J. Anderson, Explaining the acetaminophen-ibuprofen analgesic interaction using a response surface model, *Paediatric Anaesthesia*, Volume 21, Issue 12, pp. 1234–1240, Copyright © 2011 Blackwell Publishing Ltd, <http://onlinelibrary.wiley.com/journal/10.1111/%28ISSN%291460-9592>.

## Discussion

In the case example, acetaminophen was implicated as a cause of hepatic necrosis in the child. Diagnosis was delayed because CT abdominal findings, performed 3 days after the presenting injury, were misinterpreted as hepatic trauma. The pattern of necrosis described in this child's liver is consistent with damage related to acetaminophen where zone 3 is the main area of concentration of the enzyme system responsible for the conversion of acetaminophen into hepatotoxic metabolites. None of the other drugs used in his management are commonly implicated in hepatotoxicity, although co-administration of anticonvulsants may induce hepatic microsomal enzymes resulting in increased NAPQI after subsequent acetaminophen administration. While some anticonvulsant drugs may induce CYP2E1, phenytoin and phenobarbital are not metabolized through CYP2E1 and have not been considered to be CYP2E1 inducers, although there are reports that suggest phenobarbital induces a modest increase (1.7-fold) in CYP2E1 (Madan et al., 2003).

Acetaminophen has recognized hepatotoxicity after doses above 150 mg/kg in children (Penna and Buchanan, 1991), although data subsequent to this report has implicated lower threshold doses (75–90 mg/kg/day) used for 3 days or more (Kearns et al., 1998). Children may have raised serum concentrations after 2–3 days of repeated therapeutic doses, resulting in hepatic damage. Liver function is further reduced in the presence of ischaemic hepatitis, which occurs in association with severe shock and is due to a reduction in liver blood flow. The condition is manifested by elevation of plasma

hepatic transaminase concentrations with peak concentrations occurring within 24 h of the ischaemic episode. It is likely that the combination of therapeutic acetaminophen doses in the presence of a liver compromised by ischaemic hepatitis, contributed to this boy's death.

Consideration should be given to both the indication for acetaminophen and the dose in children with hepatic pathology. Acetaminophen has poor effect on temperature changes due to cerebral pathology. Temperature reduction in this child would have been better achieved by external cooling and neuromuscular blockade to prevent shivering. Acetaminophen contributes little additional analgesia and does not reduce opioid adverse effects when used to supplement morphine (Maund et al., 2011). The use of acetaminophen to control fever continues to be debated. It has not been established conclusively that the benefits of antipyretic therapy outweigh its risks (Plaisance and Mackowiak, 2000).

## CHAPTER 44

# Developmental pharmacology of opioids

Gareth J. Hathway

### Summary

Recognition of the need for alternative analgesic regimens for managing neonatal and childhood pain has led to a rich literature concerning the ways in which early life pain differs from that at older ages. As in adults, opiates are often considered the gold standard analgesic class of drugs, of which morphine is the prototypical agent. There is a wealth of data detailing clinical observations, measurements, and interventions with regard to the use of opioids in treating pain in children. Studies in the early part of this century have highlighted that, in humans, age is an important factor that influences the morphine requirement of neonates following surgery; and dose requirements are influenced by both pharmacokinetic and pharmacodynamic factors. Laboratory studies have extended our understanding of changes within the peripheral and central nervous systems that underlie alterations in nociception in early life. This chapter will review what is currently known about the actions of opioids upon nociceptive and nociresponsive elements of the nervous system in early life, how they differ from adult responses, and ask whether manipulating endogenous opioid systems in early life may have consequences on neurodevelopment.

### Introduction

The response of neonatal and young animals to pain can be generally considered to be hyperexcitable; and characterized by poorly coordinated, inappropriately organized reflexes and reduced thermal and mechanical pain thresholds (Fitzgerald, 2005). The dorsal horn (DH) of the spinal cord is important for the primary integration of somatosensory and nociceptive information in the central nervous system (CNS). Delayed maturation of inhibitory neurotransmission in the spinal cord contributes to the alterations in nociceptive responses exhibited in early life. At a cellular level this is manifested as an increased cutaneous receptive field of nociresponsive neurons in the spinal DH (Fitzgerald and Jennings, 1999). These immature physiological responses are underpinned by a lack of synaptic inhibition in the DH through the first 2 to 3 postnatal weeks in the rat (a time period which correlates with infancy through to late childhood in human development). Intrinsic spinal neurotransmitters such as GABA and glycine fail to evoke measurable mIPSCs (inhibitory currents) in the neonatal and infant spinal

cord (Baccei and Fitzgerald, 2004, 2006; Baccei et al., 2003; see also Walker and Baccei, Chapter 6, this volume).

Further sources of inhibitory drive to the adult spinal cord are descending projections from the ventral brainstem. In the adult, these projections that emanate from the rostroventral medulla (RVM) are able to powerfully facilitate and inhibit spinal excitability, increasing and decreasing spinal reflexes (Fields and Anderson, 1978; Fields et al., 1983). Furthermore, there is considerable evidence that these brainstem centres are important for the maintenance of chronic pain states in adults (Porreca et al., 2002; Zhang et al., 2009). The RVM receives a dense afferent input from the periaqueductal grey (PAG) which in turn acts as a common target for numerous more rostral structures such as the amygdala, hypothalamus, hippocampus, and anterior cingulate cortex (Fields et al., 2006; see Fitzgerald, Chapter 8, this volume). As this brief summary demonstrates, pain is a complex phenomenon involving numerous parts of the peripheral and central nervous systems. When considering the analgesic action of opioids, it is therefore necessary to consider the expression and actions of both endogenous and exogenous ligands, at multiple sites within the nervous system.

### Opioid peptides

#### History

Opium has been used as a recreational and analgesic drug for centuries, yet it was Stertörner's isolation of the active ingredient morphine in 1806 that began the pharmacological evaluation of how this drug and other similar drugs act. Some considerable time passed before the first description of specific opiate receptors (see later) (Pert and Snyder, 1973; Simon et al., 1973; Terenius, 1973). The ability of opiates to mediate analgesia in a dose-dependent manner when administered into the midbrain of rats and humans, and the observation that electrical stimulation of the same brain regions resulted in similar inhibition of pain, led to the hypothesis that an endogenous opiate-like neurotransmission system existed in the mammalian CNS (Mayer and Liebeskind, 1974; Reynolds, 1969; Tsou and Jang, 1964).

The pioneering work of many groups in the late 1960s and 1970s led to the final identification of a family of endogenous opioid-like peptides in the forebrain that were intrinsically linked with

nociception (Goldstein et al., 1979; Hughes et al., 1975; Li et al., 1976; Loh et al., 1976). The endogenous opioids include  $\beta$ -endorphin, the endomorphins 1 and 2, the enkephalins and dynorphins. Each of these are synthesized from precursor peptides: pre-opiomelanocortin (POMC), pro-enkephalin, and pro-dynorphin respectively. Work on the ontogeny of these systems was largely carried out in the 1980s and is expertly reviewed by McDowell and Kitchen (1987). Although predating developments within the field of molecular neurobiology, this is a valuable review of the subject.

### Specific peptides

*$\beta$ -endorphin* can be detected prenatally in the rat from embryonic day 13 (E13), levels increase within several brain areas with age (Ng et al., 1984) until E18 (just prior to birth at E20–21 in the rat), when adult levels have been reached (Bayon et al., 1979; Bloom et al., 1980). Analysis of the literature from this time shows general agreement that  $\beta$ -endorphin levels change postnatally, including in the pons, which has direct relevance to the descending control of pain processing. However, there is significant disagreement as to the temporal profile of these changes and the absolute levels of  $\beta$ -endorphin that can be measured in specific brain regions (McDowell and Kitchen, 1987), but marked regional differences in the development of  $\beta$ -endorphin expression in the CNS are apparent. The mechanisms for  $\beta$ -endorphin release in the brain are not fully developed at birth; both the spontaneous and potassium-stimulated release of the peptide from hypothalamic slices appear to be immature until at least postnatal day 20 (P20) in the rat (Hompey et al., 1982).

*Enkephalin* (both Met and Leu) can also be detected prenatally. Within the brainstem levels are thought to peak around the second postnatal week in the rat (McDowell and Kitchen, 1987; Ng et al., 1984) with levels then diminishing to those found in the adult. It has been proposed that the development of the enkephalinergic system proceeds in a rostrocaudal manner (Tsang et al., 1982).

*Pro-dynorphin* is the pro-peptide responsible for the synthesis of dynorphin. Studies detailing the developmental expression profile of either the pro-peptide or the actual peptide in pain related areas of the CNS are very sparse and no clear consensus or opinion has been reached (McDowell and Kitchen, 1987).

### Developmental expression

It is apparent from the current literature that investigations into the normal development of the endogenous opioid system have slowed considerably from the late 1980s and early 1990s. There is little data regarding the presence of endogenous opioid peptides in the primary afferent fibres through postnatal development. There is limited evidence for the presence of opioid peptides in some afferent fibres in the prenatal environment (Haynes et al., 1982), but this weak immunoreactivity disappeared postnatally and was restricted to white matter tracts. Fibre staining within the spinal DH was absent. This study pre-dated a full description of the composition of the family of opioid peptides and concentrated only on the expression of  $\beta$ -endorphin. More recent studies regarding the distribution of these peptides in the peripheral nervous system has focussed on the adult rat. In these studies (Marvizón et al., 2009), although enkephalin was never observed to be co-localized with primary afferent terminals in the spinal DH, there was some co-localization of dynorphin with calcitonin gene-related peptide (CGRP), a marker of peptidergic C fibres. A thorough study through postnatal development has not yet been performed.

## Impact of developmental interventions on opioid systems

### Stress and maternal separation

Subsequent research has focussed on pre- or perinatal manipulations to either the rat pups or their mothers, and the impact this has upon the development of opioidergic systems, particularly in the forebrain (Belcheva et al., 1998; Lin et al., 2009; McLaughlin et al., 2002). Most of these manipulations take the form of stress such as maternal separation in the early postnatal period, or of pharmacological manipulations such as exposure to opiates whilst *in utero*. The overriding hypotheses of these studies are that the ontogeny of the opioidergic system in the CNS will be altered, and there is considerable supporting data. In one example (Gustafsson et al., 2008), rats were either collectively or individually separated from their mothers for 15 or 360 min over the first three postnatal weeks. This resulted in altered met-enkephalin and dynorphin levels in a number of forebrain regions in 3-week and 10-week old offspring, and this was particularly pronounced if pups were individually separated. Whilst many areas of the brain were assayed, focusing on the PAG which is directly involved in pain processing, it can be seen that the normal increase in met-enkephalin levels seen in control rats is blunted in rats that underwent separation, with inconclusive changes in dynorphin levels. This study, which is one of many, demonstrates that early life interventions can radically change the expression and therefore the functional role of endogenous opioid systems through to adulthood.

### Opioid exposure

Clinically it is important to determine whether exposure to opiate analgesics early in life has any effect on subsequent response to the same compounds later in life. In rats, administration of opioids either prenatally to the mother, or in the first 10 postnatal days, can significantly shift the morphine dose–response relationship later in life. Single morphine administration on postnatal days 1 or 2 (1 mg/kg) produced ‘tolerance’ to subsequent morphine analgesia at postnatal day 29 (Bardo and Hughes, 1981). Repeated administration of morphine over the first 9 postnatal days (3 mg/kg subcutaneously) resulted in significantly lower basal thermal and mechanical thresholds in the juvenile period (P29). Additionally, there was a significant rightward-shift in the cumulative dose–response curves at both postnatal days 20 and 49 (Zhang and Sweitzer, 2008). Prenatal exposure (twice daily from E5 to E12) altered morphine dose–response in offspring at postnatal day 35 (O’Callaghan and Holtzman, 1976). These data suggest that opiate exposure early in life can alter the development of components of the nervous system necessary for mediating the analgesic effects of exogenous opioids; and also that early life opiate exposure can alter other elements of the ‘pain pathway’ development as indexed by alterations in basal sensory thresholds in some studies (Zhang and Sweitzer, 2008).

### Role of opioid peptides in normal development

Do opioid peptides have a role in normal development? Reviewing the available literature suggests that opioid peptides act as inhibitory growth factors at a cellular level, with antagonism of opioid receptors *in vivo* resulting in increased dendritic length and spine

formation in neurons in the cerebellum (Hauser et al., 1987, 1989). However, alterations in the anatomical development of the nervous system by opioids are not restricted to neurons. Astrocyte numbers have decreased in mouse cortical cultures exposed to met-enkephalin by a receptor-dependent mechanism (Stiene-Martin and Hauser, 1990). More recently this effect of opioids on the development of non-neuronal cells in the nervous system has been confirmed. To model effects of prolonged opiate exposure of offspring of opiate-dependent mothers, Sanchez et al. (2008) implanted pregnant rat dams with osmotic mini-pumps that continuously delivered buprenorphine from day 7 of gestation until postnatal day 21, ensuring that pups were exposed prenatally to the drug via the placenta and postnatally via maternal milk. In these pups it was shown that lower doses of buprenorphine increased the expression of myelin basic protein whilst higher doses significantly decreased levels of this protein, particularly when animals were examined at postnatal day 12. Anatomical examination of the corpus callosum showed that in rats exposed to buprenorphine there were significantly more large calibre myelinated fibres but the same distributions of non-myelinated fibres compared to controls. This increase in calibre was also associated with a thinner myelin sheath surrounding these axons suggesting an altered balance between axon growth and myelin thickness. Thus, exposure to high levels of opioid for relatively prolonged periods during prenatal development can alter CNS structure. Further studies are required to evaluate the impact of different doses and durations of exposure during postnatal development.

More recently data from our laboratory has demonstrated a specific trophic role for endogenous opioids in the maturation of supraspinal centres responsible for the descending control of spinal pain processing (Hathway et al., 2012). In this study we implanted subcutaneous mini-pumps containing naloxone HCl at P14, P21, or P28, and continuously delivered the drug for 7-day periods. Animals were then allowed to mature to P40. In the group that had drug delivered between P21 to P28, the RVM failed to mature properly, and descending inhibition of spinal pain processing could not be evoked in adulthood. These data showed that the action of endogenous opioids are central to the normal maturation of supraspinal pain control systems, but even more interestingly that this occurs relatively late in postnatal development, at a period when rats would be judged to be adolescent. This is a true 'critical period' as the same manipulation one week before or after this does not prevent or effect normal maturation. In an extension of this study we implanted neonatal, 7-day-old, rats with mini-pumps that delivered morphine for 7 days and showed that at developmental stages where the RVM is normally immature and unable to provide descending inhibitory control of spinal processing, that neonatal morphine treatment had accelerated the maturation of the RVM. In these animals adult like stimulus response profiles from the RVM were evoked. This work demonstrates the importance of the opioidergic system for the normal postnatal development of pain processing in the nervous system.

It is intriguing to speculate on the results of studies using more recent quantitative and non-quantitative methods to further evaluate the changing expression of opioid peptides in the developing nervous system. The majority of studies listed above utilized the most sensitive assays available at the time, such as radioimmunoassay and *in situ* hybridization. The value of these studies remains high and they are still our best source of information regarding the

ontogeny of adult endogenous opioid networks in the CNS, however the application of quantitative genomic and post-genomic techniques would significantly add to this work. Equally, utilizing immunohistochemical techniques to uncover the distribution of these peptides and the co-transmitters utilized in different neuronal populations through the postnatal period would be valuable. Many of the supraspinal structures involved in pain modulation are anatomically small and the analyses detailed earlier were too crude to detect subtle variations in expression levels within refined brain nuclei. Even with today's state-of-the art RNA amplification methods accurately and repeatedly dissecting these areas from postmortem tissue is technically challenging.

## Opioid receptors

Opioid peptides mediate their effects via interactions with a family of opioid receptors, which are metabotropic, membrane-expressed receptors that act through second messengers (i.e. in contrast to ionotropic receptors that form an ion channel pore). There are three main subclasses of opioid receptor named mu ( $\mu$ ), delta ( $\delta$ ), and kappa ( $\kappa$ ), as well as a less well recognized and investigated receptor, ORL-1 (opioid-like receptor). Receptors are composed of seven hydrophobic membrane-spanning domains, with extracellular components that are involved in specifying interactions with ligands, and intracellular domains that interact with intracellular signalling mediators. Opioid receptors mediate their actions via second messenger G-proteins (see later). In the adult nervous systems activation of opioid receptors engage intracellular signalling systems that are in large part inhibitory, and act to decrease neuronal excitability by increasing inwardly rectifying potassium ( $K^+$ ) conductances, decreasing voltage-dependent calcium ( $Ca^{2+}$ ) channels, and by decreasing the production of cyclic adenosine monophosphate (cAMP).

## Peripheral nervous system

The peripheral nervous system detects stimuli and conveys sensory information to the CNS. Peripheral sensory afferent neurons are subdivided into three broad categories according to their physiological and anatomical properties:

- ♦ A $\beta$  fibres are large, myelinated fibres that usually convey non-noxious information to the CNS.
- ♦ A $\delta$  fibres are small myelinated fibres and convey both noxious and non-noxious information.
- ♦ C fibres are small unmyelinated fibres that convey noxious information to the CNS, that are further subdivided into peptidergic or non-peptidergic, depending on their neurotransmitter phenotype.

All of these primary afferent fibres innervate target tissues such as skin, muscle, and viscera and their cell bodies are to be found in the dorsal root ganglia (DRG) which run parallel to the spinal cord. These neurons then have spinal projections which enter the DH of the spinal cord. Each primary afferent subtype has different central termination patterns within the DH. These terminations are immature at birth and refine to their adult state via activity dependent processes (see Walker and Bacceti, Chapter 6, this volume).

A detailed study of the expression pattern of  $\mu$ -opioid receptors in the DRG over postnatal development has shown considerable changes in early life (Nandi et al., 2004). Receptor expression in

adulthood was confined to mainly small and medium sized neurons (presumably C and A $\delta$  fibres). However, in the neonatal rat, there were significantly more  $\mu$ -opioid receptors expressed on large-diameter myelinated fibres (Beland and Fitzgerald, 2001). This increased expression was mirrored when Ca<sup>2+</sup> imaging demonstrated increased fluorescence in response to activation of the  $\mu$ -opioid receptor with the receptor agonist DAMGO, in a greater proportion of DRG neurons than in the adult (Nandi et al., 2004). This suggests that not only are more receptors present, but they are also functional and can be activated by agonists, as confirmed by an enhanced response or leftward shift in the dose–response relationship for systemic morphine in younger rats. The mechanisms that regulate the expression of the  $\mu$ -opioid receptor in primary afferent neurons are not known. Although age-dependent alterations in the central terminals of primary afferent neurons in the DH are related to changes in levels of neural activity (Beggs et al., 2002; Bremner and Fitzgerald, 2008), it is not known if opioid receptor expression is similarly regulated. Both the  $\kappa$  and  $\delta$  subtypes are expressed on the terminals of adult primary afferent neurons, but developmental changes have not been evaluated.

The presence of opioid receptors on the terminals of primary afferent neurons suggests a role in inhibiting primary afferent firing in response to noxious stimuli. In postnatal rats, electrical stimulation of incoming fibres in the dorsal root produces excitatory postsynaptic potentials in the DH; but these were reduced by the  $\mu$ -opioid receptor agonist DAMGO via inhibition of both A $\delta$  and C fibres. DAMGO was also more efficacious and potent at inhibiting C fibres than A $\delta$  fibres, but identical intracellular processes mediated the inhibition in both fibre types. Tissue from 17- to 25-day-old rat pups, which is toward the limit of technical feasibility of the techniques employed were used, but these are not fully mature animals (Heinke et al., 2011). It was not reported whether stimulating the dorsal root at A $\beta$  strengths was also sensitive to DAMGO application in young animals, as would be predicted on the basis of developmental studies (Nandi et al., 2004).

## Spinal cord

The spinal cord is the first site of integration of sensory information within the CNS. Primary afferent sensory neurons enter the spinal cord via the dorsal root and synapse with second-order neurons. These second-order neurons are central to the perception of pain; being intrinsically involved in both the transmission of nociception-related information to supraspinal centres, and also in receiving converging descending information from other supraspinal sites that can act to increase or decrease their excitability. Autoradiographic and immunohistochemical studies have shown that the majority of opioid receptors are located either in laminae I and II of the DH and to a lesser extent in deeper layers (Besse et al., 1990; Rahman et al., 1998). This reflects termination of primary afferents (see earlier), but approximately 30% (Besse et al., 1990) of receptors are located postsynaptically and may relate to descending projections.

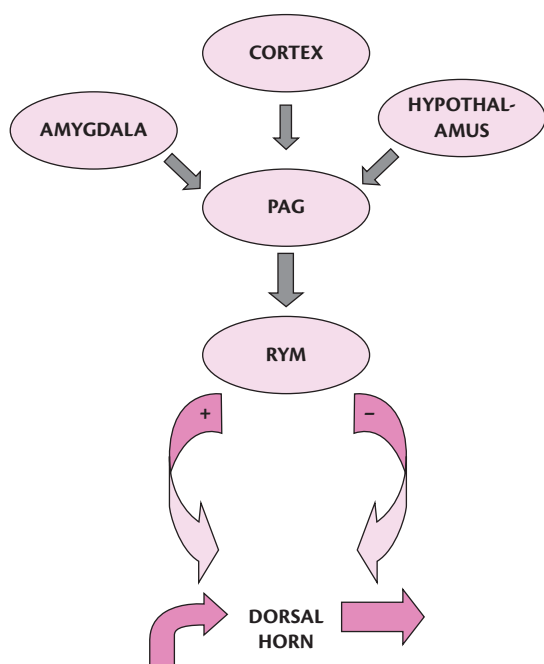

Studies in the 1990s using *in situ* hybridization illustrated that mRNA for at least the  $\mu$ - and  $\kappa$ -opioid receptors can be found within the DH (Maekawa et al., 1994). The highest density of mRNA for the  $\mu$ -opioid receptor could be found in laminae I, II, and VIII whilst  $\kappa$  was densest in laminae I and II. Recent immunohistochemical studies examined the anatomical distribution of

$\mu$ -,  $\delta$ -, and  $\kappa$ -opioid receptor expression in the spinal cord, with intense staining to all three seen in the superficial layers in adult rats (Gray et al., 2006). Positive cells were generally ovoid in shape and aligned to follow the rostrocaudal axis of the spinal cord itself.  $\mu$  staining was most intense in lamina II and was localized to the cell membrane of cell bodies and dendrites, whereas  $\delta$  immunoreactivity was restricted to cell bodies.  $\kappa$  staining was particularly intense in lamina I due to the presence of heavily stained fibres, but cell body staining was also prominent here. Immunohistochemistry uses antibodies to selectively label different proteins and provides increased spatial resolution, as protein expression can be directly detected at a subcellular level. This is a distinct advantage over other techniques, such as radioligand binding, which requires tissue to be exposed to irradiated drug and resultant images on X-ray or similar films to then be analysed. Improvements in immunohistochemical technologies, from antibody design and production, through to signal amplification and advances in microscopy, have meant that immunohistochemistry is now more routinely employed in laboratory studies, but to date there has been limited immunohistochemical investigation of the postnatal expression of opioid receptors in the spinal cord.

Autoradiography has been used to map postnatal changes in opioid receptor binding in the spinal cord (Rahman et al., 1998). At birth,  $\mu$  binding is relatively diffuse, increases over the first postnatal week, and then decreases until P21. A progressive pattern and refinement of  $\mu$  binding could be seen with increasing age, so that binding sites became progressively more restricted to the superficial laminae of the DH as seen in the adult.  $\kappa$  binding followed a similar pattern to  $\mu$  in that diffuse binding was present at birth. Total  $\kappa$  binding increased over the first postnatal week and then decreased so that at P14 there was approximately 50% of the binding seen at P7. At P21 and P56 (adult) greater preference for  $\kappa$  binding in the superficial DH was observed.  $\delta$  opioid receptor binding was not present at birth, was first observed at P7, but was diffuse and remained like this until at least P56.

## Brainstem

Analysis of the published literature shows that, as with other areas of the nervous system, a detailed account of the postnatal development of opioid receptors is elusive. For the purposes of this chapter, changes in opioid receptor expression that take place in areas of the brain that are recognized as being central to the modulation of spinal cord excitability, namely the PAG and the RVM, have been highlighted (Figure 44.1). Immunohistochemical studies (Gray et al., 2006) have shown intense immunoreactivity for all three opioid receptors within the PAG; with considerable co-localization of  $\mu$  and  $\delta$  receptors in the medial and lateral parts of this midbrain structure. Light to moderate  $\kappa$  staining was seen and  $\kappa$  positive cells were closely apposed to those that expressed  $\mu$  opioid receptors.  $\kappa$  immunoreactivity was also most noticeable within the caudal and ventrolateral parts; the latter is of particular interest as it is this part of the PAG that projects to the RVM. Within the nucleus raphe magnus of the RVM strong  $\mu$  staining was seen in dense cell bodies whereas  $\delta$  immunoreactivity was associated with fibres and was more diffuse. As in the PAG there was some co-localization of both  $\mu$  and  $\delta$  receptors. Small round cells which were positive for  $\kappa$  immunoreactivity were noted to be ‘intermingled’ with  $\mu$  positive cell bodies. The locus coeruleus (LC) is the source of noradrenaline

**Figure 44.1** Supraspinal modulation of dorsal horn excitability. The ability of supraspinal sites to control the excitability of neurons within the dorsal horn of the spinal cord is one of the major mechanisms that underpin opioid analgesia. Forebrain regions commonly innervate the periaqueductal grey (PAG) which in turns innervates the rostromedial medulla (RVM). Via spinally projecting neurons this structure directly controls pain processing in the spinal cord. The RVM bi-directionally controls spinal excitability it is able to both facilitate (+) or inhibit (–) the spinal cord depending on the nature of the input to the RVM itself. The RVM is therefore central to opioid analgesia mediating these effects via descending inhibitory pathways and in the maintenance of chronic pain states via facilitatory pathways.

for the entire central nervous system and also has descending projections which powerfully control spinal excitability. Intense  $\mu$  staining was found within cell bodies of the LC in adult rats;  $\delta$  staining although above background levels was weak; and a few  $\kappa$ -positive cells were present (Gray et al., 2006).

Multiple radioligand binding studies have quantified opioid receptor binding at different postnatal ages in brain tissue. In general, it appears that the expression of opioid receptor binding sites within the brain alters with age and that the different opioid receptors follow different trajectories (Kitchen et al., 1990; McDowell and Kitchen, 1986, 1987; Spain et al., 1985; Volterra et al., 1986). Despite the difficulty in making comparisons between studies it appears that  $\mu$  receptors are present at birth and are able to bind ligands with the same affinity (dissociation constant,  $K_d$ ) as in the adult. Binding of  $\mu$  selective ligands increase from birth and reach adult levels around the third postnatal week.  $\delta$  receptors seem to be absent at birth, but reliable binding is detectable from the second postnatal week, and then increases with age.  $\kappa$  binding is detectable at P5, increases to high levels by P10, then decreases to adult levels by P25. Binding characteristics of the  $\delta$  and  $\kappa$  receptor are the same in neonates as they are in adults. Whilst informative, these studies provide no data regarding the expression of opioid receptors in specific brain nuclei. Most use whole brain homogenates which have limited sensitivity, and Spain et al. (1985) use rostral and caudal brain portions. It is not unreasonable to hypothesize that as well as following different paths between subtypes, the maturation of opioid

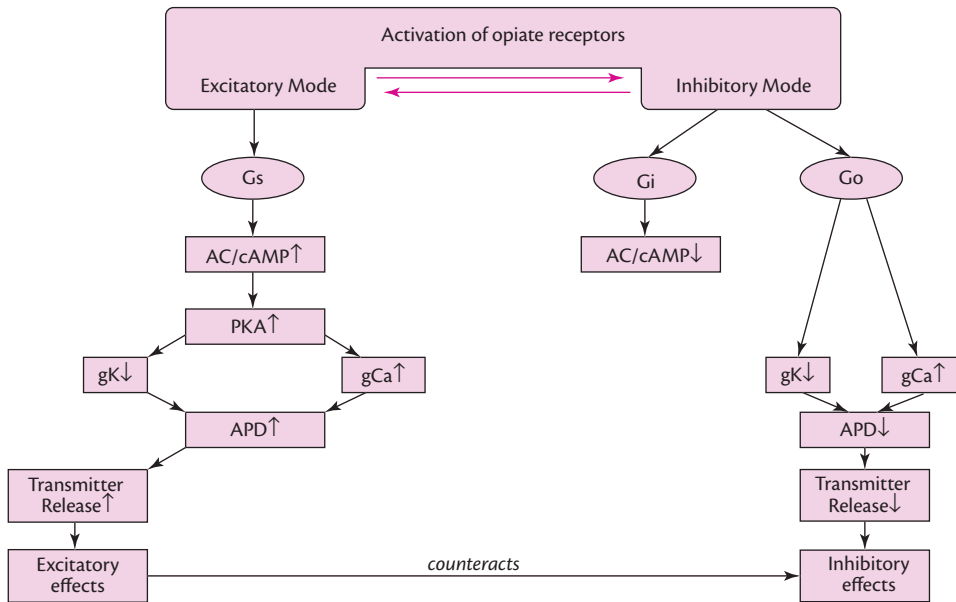

receptors may follow different trajectories in different regions of the brain. Again the application of modern post-genomic approaches to the study of the development of opioid receptor expression and their pharmacology is required.

### Idiosyncrasies of age and receptor function

It is tempting to think of neonates, children, or young animals as smaller versions of adults. Compensations are clearly made in terms of the dosing requirements based on weight and pharmacokinetic data, but what of the fundamental action of the drug at its receptor? Previously we have shown that the action of midazolam at the  $GABA_A$  receptor is significantly altered in neonatal rats as it is pronociceptive and fails to produce sedation (Koch et al., 2008). Could the result of opioid receptor agonism also undergo age-dependent changes? As discussed previously, there seem to be no major differences in the basic receptor-agonist interaction with postnatal age as assessed by radio-ligand binding in whole brain homogenates. It must be stressed that the available literature confirms that opioid mediated analgesia can be evoked at all ages. This is true via whichever route the drugs are administered; be that systemic (Abbott and Guy, 1995; Nandi et al., 2004; Thornton et al., 1998), epidural (Marsh et al., 1999a, 1999b), intrathecal (Barr et al., 1992; Westin et al., 2010) or peripherally (Barr, 1999).

Assumptions seem to have been made in the literature that  $\mu$ -opioid receptor activity–function relationships in one part of the CNS reflect the situation in the entire CNS. Recently we have shown that this is not the case. Microinjection of the  $\mu$ -opioid receptor agonist DAMGO into the RVM of juvenile (P21) rats is able to dose-dependently facilitate spinal nociception, that is it increases pain, which is in contrast to adult (>P40) rats where the same intervention results in dose-dependent analgesia (Hathway et al., 2012). This alteration in response to receptor agonism is not associated with an age-related alteration in the level or pattern of expression of  $\mu$ -opioid receptors within the RVM, but seems to be a fundamental shift in the signalling pathways activated by the receptor following its activation. It is therefore apparent that although the same receptor can be expressed within the same animal in multiple tissues at any point during postnatal development there can be subtle, tissue specific alterations in the receptor that radically alter the consequences of its activation.

Analysis of the literature reveals some interesting developmental changes. There are age-related *increases* in the total  $\mu$ -opioid expression within the brainstem of the developing rat whilst there is a concomitant *decrease* in  $\delta$  expression (Kivell et al., 2004). It was also been noted that MOR in brainstem tissue existed as two different isoforms, both a 50 kD protein and a 70 kD protein, and that levels of the heavier isoform increased with postnatal age whilst the lighter isoform decreased. No alteration in the expression pattern of  $\mu$ -opioid receptor was seen, in agreement with our later study (Hathway et al., 2012). This age-related alteration in receptor mass may represent alterations in: the splicing of mRNA for the receptor; post-translational glycosylation; use of alternative promoters for the *OPRM1* gene that encodes the receptor; or oligomerization of the receptor. Several studies have noted region specific distribution of  $\mu$ -opioid receptor splice variants across the adult rodent CNS (Abbadie et al., 2000a, 2000b; Pan et al., 1999; Schulz et al., 1998), yet this study was the first to detail an apparent change in receptor isoform expression that correlated with postnatal age.

**Figure 44.2** Bi-modal actions of opioid receptors. Classical opioid receptors act in an inhibitory mode mediating their actions via Gi and Go pathways, decreasing production of cAMP, reducing calcium currents and increasing potassium currents which ultimately leads to decreased neurotransmitter release. Alternatively opioid receptors can operate in an excitatory mode (at certain times in postnatal development or in states of opiate tolerance). In this mode receptors operate Gs (stimulatory) pathways increasing calcium currents and cAMP levels with increase neurotransmitter release.

Another age-related alteration in opioid receptor pharmacology is the propensity of neonatal opioid receptors to weakly couple to their effector mechanisms. This is thought to be due to modifications in the way that the receptor interacts with G-proteins (Figure 44.2). All opioid receptors couple to Gi G-proteins and therefore have inhibitory effects on cellular excitability. The classic view of the intracellular events that take place following activation of the receptor is that  $K^+$  currents are increased and  $Ca^{2+}$  currents are decreased, leading to a decrease in neurotransmitter release from the neuron (Crain and Shen, 1998). However, what if this is too simple an explanation? Evidence for altered  $\mu$ -opioid receptor G-protein coupling was first observed in 2003 (Nitsche and Pintar, 2003), when this group demonstrated radioligand binding to the receptor prior to agonist stimulated [ $^{35}$ S]GTP $\gamma$ S production in embryonic brain. Within the striatum of the postnatal rat, there is an age-dependent increase in Gi  $\mu$ -opioid receptor coupling with postnatal age (Talbot et al., 2005); with levels of Gi coupling at P15 approximately 50% of those in the adult, and maximum levels of Gi coupling not being achieved until greater than P40 (approximately 250 g body weight). Further work is required to establish the functional consequences of this, but it implies that if the  $\mu$ -opioid receptor is not coupled to Gi then it must either be coupled to some other G-protein, or is functionally inert and has no physiological role. However, this previous study concentrated on opioid signalling within the basal ganglia, and this may not be the case in areas more pertinent to pain. We, and others, have clearly shown functional responses to opioid in the RVM (Hathway et al., 2012), but further work in different brain regions is required.

## Conclusion

Developmental alterations in opioid pharmacology from the laboratory experimental perspective are complex, and based on a solid but

dated literature that has not applied modern post-genomic methodologies, and without a full appreciation that neonatal and young animals are not just smaller versions of adults. Behavioural studies clearly demonstrate analgesic responses to opioids from early development, but changes in opioid receptor expression and signalling mature at different rates in different parts of the nervous system, and this contributes to age-related differences in the degree and nature of response. In the coming years it is hoped that fresh approaches to evaluating postnatal alterations in opioid systems may shed new light on the role that endogenous and exogenous opioids may play in neurodevelopment, and potentially allow for the development of new therapies that take into account the ontogeny of the opioidergic system.

## CHAPTER 45

# Opioids in clinical practice

Scott A. Strassels

### Introduction

Opioid analgesics occupy a unique position in modern medicine. They are indispensable tools for the treatment of many types of moderate to severe pain, but are also the focus of intense attention and criticism in the biomedical literature, lay press, and media (Meldrum, 2003; Whelan et al., 2011).

The epidemiology of painful conditions and diseases, as well as other common sources of pain, including invasive procedures to diagnose and monitor diseases, help provide insight into the need at the population level for opioids to provide safe and effective prevention and management of moderate to severe pain. At the patient level, the importance of these medications is illustrated by tools such as the World Health Organization (WHO) pain ladder (Ventafridda et al., 1985), in which opioids are central to steps two and three, and by the inclusion of morphine in the WHO essential medicines list of priority medicines for mothers and children (World Health Organization, 2011a), the WHO *Model List of Essential Medicines for Children, 3rd list*, published in March 2011 (WHO, 2011b), and the WHO guidelines on the pharmacological treatment of persisting pain in children with medical illnesses (WHO, 2012).

Nonetheless, there is mixed consensus about the roles opioids play in society and medical practice, particularly as part of the care of persons with chronic, non-cancer pain. In part, this state of affairs is due to our evolving understanding of opioids and their effects at the individual and population levels, to limited time spent educating clinicians on the appropriate use of these and other analgesics, and to substantial gaps in the evidence base, overall and particularly within children (Chou et al., 2009a, 2009b; Chapman et al., 2010). Despite this uncertainty, the view of morphine, and by extension, other opioids, as not just important, but absolutely essential contributors to clinical practice underscores the belief that these are among the most useful medications of any sort. Yet, while the medications in this class have numerous advantages, including a high degree of effectiveness and safety when they are used appropriately, there are important patient and population issues and concerns regarding the use of these medications. As a result, it is critically important that all medical practitioners, as well as other clinical decision-makers be familiar with the pharmacological and pharmacodynamic characteristics and effects of these agents, as well as related issues that are of interest, such as opioid-induced hyperalgesia (OIH) and efforts to address inappropriate opioid use at the population level.

### Clinical outcomes associated with use of opioids

Evidence-based medicine plays an important part of clinical practice in many countries, from reimbursement decisions through pay for performance incentives. Yet, the evidence base for the use of opioids in children with painful conditions is uneven. The result of this situation is that there are few clinical practice guidelines (CPGs) focused on specific treatments for pain in children and adolescents. In the absence of high-quality evidence, clinicians are often left to practise according to habit, which may or may not result in optimal outcomes. Furthermore, there is a lack of consensus on the outcomes that are best to assess. For example, it is generally easy to assess a patient's pain (and, indirectly, the quality of care) using a numeric analogue 0 to 10 or verbal rating scale, but pain intensity is just one of many facets of a complex multidimensional experience (Gordon et al., 2005). Other dimensions of the pain experience, such as the ability to function in ways that are important to the patient, family, and caregivers, are also likely to be important.

To illustrate the current state of the biomedical literature on this topic, a literature search using the strategy [(pediatric OR paediatric) AND pain AND clinical practice guideline AND opioid] identified ten English-language, Pubmed-indexed papers published between 2007 and 2012. Of these, two were guidelines based on a systematic review of the literature. In one, the authors reviewed papers and abstracts published between 1996 and 2006 to provide recommendations for treatment of chronic and procedural pain in paediatric patients with rheumatic disease (Kimura and Walco, 2007). The other guideline provides recommendations from the Canadian Pain Society for drug treatment of neuropathic pain, and while none of the contents are specific to paediatric patients, it makes sense that the insights may be used in caring for children as well as adults (Moulin et al., 2007). Other topics identified in this search included the use of intravenous (IV) bolus morphine in a paediatric setting (Ellis et al., 2011), regulatory aspects of paediatric pain management in Europe (Fortinguerra et al., 2010), use of the WHO analgesic ladder to provide pain management to 39 children with leukaemia in a teaching hospital in India (Geeta et al., 2010), the results of a survey on the effect of guidelines on pain management in Austrian, German, and Swiss neonatal intensive care units (Gharavi et al., 2007), and the results of a survey of paediatric anaesthesiologists in the US, published in 2010, which was undertaken to describe patient demographics, as well as whether

IV patient-controlled (or proxy-controlled) analgesia was available and used, and the degree to which serious and life-threatening opioid-related adverse events occurred (Nelson et al., 2010). Among other findings, these authors reported that facilities with more paediatric beds were more likely to have a paediatric pain service, that IV patient-controlled analgesia was available at nearly all of the 252 institutions surveyed, and that only 38% of these institutions offered IV proxy-controlled analgesia.

Other CPGs have also been published. In 2012, an updated practice guideline was published by the American Society of Anesthesiologists for acute pain management in the perioperative setting (American Society of Anesthesiologists, 2012). While not specific to children, this document includes general recommendations for assessing, preventing, and treating pain in paediatric patients. The National Comprehensive Cancer Network (NCCN) has also published guidelines for the treatment of paediatric cancer pain in the past, most recently in 2007 (National Comprehensive Cancer Network, 2007). While the recommendations in this CPG are primarily based on lower-level evidence, including consensus, the authors recommend that treatment be titrated to pain intensity and the patient's clinical condition, reflecting the understanding that pain affects and is affected by many other dimensions of the pain experience besides just intensity. The Association of Paediatric Anaesthetists of Great Britain and Ireland published the second edition of *Good Practice in Postoperative and Procedural Pain Management* in 2012. This document is useful not only because it provides recommendations by age (i.e. procedural pain in the neonate versus older children), it also addresses assessment systematically, using explicit criteria for the evaluation of evidence. Thus, while pain intensity is clearly important, other issues, such as distress, consolability, and parental report are also discussed.

The 2012 WHO guidelines on the pharmacological treatment of persisting pain in children with medical illnesses is important for three main contributions (World Health Organization, 2012).

First, this guideline focuses on chronic pain and excludes pain due to trauma, surgery, or invasive procedures, although the recommendations are likely to apply to other patient populations, in other settings, and with other types and sources of pain. It also includes strength of recommendation and quality of evidence ratings. For example, one such guideline is that 'the use of strong opioids is recommended for the relief of moderate to severe persisting pain in children with medical illnesses' (recommendation 4, World Health Organization, 2012). Although this statement is rated as a strong recommendation, the quality of evidence supporting this suggestion is low. Notably, it is unlikely that the strength of evidence for this and similar statements will be addressed. In order to strengthen the quality of evidence, it would be necessary to conduct well-designed clinical and epidemiological research to compare the ability of strong opioids to other drugs and non-pharmacological approaches to treat moderate to severe pain in medically ill children with persisting pain—an effort that would bring up questions of appropriate and ethical resource use.

The second contribution made by the 2012 WHO guidelines is explicit discussion of codeine and tramadol—drugs that were excluded from these recommendations. Codeine, a prodrug with analgesic activity due to its conversion to morphine via cytochrome P450 (CYP) 2D6, was excluded because of problems with safety and efficacy due to the variability caused by genetic polymorphism in that metabolic pathway. Further, fetal CYP2D6 activity is extremely

low compared to adult levels, and rises to no more than 25% of the adult level in children under 5 years of age. The result has been no analgesia from codeine (in poor or low metabolizers) and potential toxicity due to increased morphine production at the other end of the spectrum of activity. Tramadol was excluded due to a lack of evidence for its use in this patient population, and lack of regulatory approval for paediatric use in some countries.

The third major contribution in the new WHO guidelines is a two-step approach to the choice of medications, as opposed to the three-step ladder used in previous WHO publications. In this new method, the first step consists of treatment for mild pain using acetaminophen (paracetamol) and ibuprofen. In contrast to the three-step WHO ladder, the second step now consists of adding a strong opioid to non-opioid therapy for moderate to severe pain.

Underlying these CPGs, there is also a small group of clinical trials that assess opioid use perioperatively or in specific painful conditions. Using the strategy [(child\* OR pediatric OR paediatric) AND outcome AND opioid AND pain], 207 articles published between 2007 to 2012 were identified. Of these, 30 papers remained after a review of the titles and abstracts. One paper assessed the use of all opioids in US emergency departments for any diagnosis (Pletcher et al., 2008). Several papers were reviews: one of opioid pharmacogenomics in the perioperative setting, one of analgesia in neonates (Allegaert et al., 2009), and one of the pharmacotherapy for acute pain in children (Mak et al., 2011). Additionally, one paper was a systematic review of the effect of a continuous infusion with IV patient-controlled analgesia on respiratory depression, and one was a report from a Food and Drug Administration workshop on the design of paediatric analgesic clinical trials (Berde et al., 2012).

When considered as a group, the outcomes assessed in these papers typically emphasized pain relief, whether a drug or route of administration was used, or an adverse event occurred, rather than the result of care for the patient. For example, outcomes reported included the occurrence of adverse events (Ou et al., 2008), whether opioids were used in children with abdominal pain who presented to an emergency department (Goldman et al., 2008), the use of patient-controlled analgesia in children at the end of life (Schiessl et al., 2008), and the use of ketamine as a way to decrease morphine use in children who underwent tonsillectomy (Abu-Shahwan, 2008). In one trial, changes in pain intensity were compared between children who received ibuprofen and those who received acetaminophen with codeine for extremity injuries (Friday et al., 2009). Other outcomes studied included quality of sleep, play and level of activity, eating, speech, and cry (Ruggiero et al., 2013), assessment of pain compared to hospital standards (Vijenthira et al., 2012), and emergence delirium, emesis, hypoxaemia, and the need for airway intervention in a group of children who underwent bilateral myringotomy and placement of ventilating tubes (Hippard et al., 2012). Notably, in this last paper, although administering drugs by intramuscular injection is not recommended due to pain and unpredictable absorption from tissue, the authors of this study concluded that the intramuscular route would be preferred due to the lack of a difference in the efficacy of intranasal fentanyl, intramuscular, or intravenous morphine, and the utility from the clinician's perspective of avoiding having to establish vascular access and the potential for laryngospasm from intranasal medications.

## Pharmacokinetics

Pharmacokinetics refers to how physiological processes affect the absorption, distribution, metabolism, and excretion of drugs—in short, these processes are often referred to as what the body does to the drug, as opposed to pharmacology or pharmacodynamics, which are what the drug does to the body (Benet, 1984). The aspects of pharmacokinetics are absorption, distribution, metabolism, and elimination. Each of these phases includes issues that may affect use of the opioids in paediatrics.

### Absorption

The stratum corneum is structurally complete by 34 weeks of gestation, and in a term infant, continues to thicken until about 4 months of age (Maples et al., 2006). Since younger infants have greater water loss than older infants as a function of body surface area: body weight, preterm infants and term infants early in life have greater absorption of drugs through the skin than older children and adults, potentially making the transdermal route more efficient in younger infants, although the changing nature of the skin also presents important challenges (Maples et al., 2006, p. 214).

Prodrugs are inactive, and require transformation to become active. As a result, activity of these medications may be decreased if enzymatic activity is insufficient to produce the active drug (as in preterm infants); lipophilic drugs may be absorbed erratically secondary to evolving lipolytic capacity; bile acids may be diminished, resulting in changes in enterohepatic recirculation of glucuronidated metabolites (morphine, hydromorphone), absorption may be increased, as a function of delayed gastric emptying and gastrointestinal transit time, which can be affected by diet.

Rectal administration may be useful when administration of meds orally or by other routes is not available, but absorption may be unpredictable (Birmingham et al., 1997; Nolke 1956). One study of 48 persons after minor surgery found that the amount of oxycodone was absorbed from a rectal suppository was similar to that from the oral route, but was about 42% of the IV dose (Leow et al., 1992). In healthy, young men, approximately bioavailability of rectal hydromorphone was approximately 33% (Parab et al., 1988).

The nasal and transmucosal routes of administration have also become popular. For example, in the US, fentanyl is available as a buccal tablet, a transmucosal lozenge, which is rubbed on inside of the cheek, a nasal solution, and a sublingual spray. It is critically important to note that these products are not bioequivalent and cannot be used interchangeably without careful titration.

### Distribution

Total body water accounts for approximately 75% of total body weight in a newborn infant and about 92% in premature infants, gradually decreasing to 60% at 6 months of life (Friis-Hansen 1971, 1983). Similarly, extracellular fluid accounts for a greater percentage of total body weight than in adults (45% at birth (50% in premature infants), 28% at year 1, 20% for adults). The result is that water-soluble drugs, such as morphine, have a larger volume of distribution. In contrast, the amount of body fat increases over the first year of life before decreasing over time to adult levels. Fat levels as a percentage of body weight are higher in girls than boys during adolescence. The implication here is that fat-soluble drugs (among the opioids, diamorphine, fentanyl, alfentanil, and sufentanil are more lipophilic than morphine) may have a longer duration of

action for infants compared to older children and adults, as well as in adolescent girls compared to adolescent boys.

In general, once absorbed into the bloodstream, a given drug must be free (unbound) in order to be pharmacologically active. As a result, the degree to which drugs are bound to plasma proteins has the potential to influence medications; this fraction can be affected by the concentration of the protein, the affinity of the drug for the protein, and the ability of the protein to interact with the drug (Maples et al., 2006, p. 217). As a result, in persons with hypoalbuminaemia or in persons with conditions in which the binding sites on albumin for a drug are altered and binding is decreased, pharmacological activity of a drug is likely to be increased. Acidic drugs are generally bound to albumin, while basic drugs are bound to alpha-1 acid glycoprotein. For example, albumin levels are lower in premature than in term babies, and there are fewer binding sites. In neonates, alpha-1-acid glycoprotein is present, but at about one-third of adult levels, which occur at approximately 1 year of age.

The opioids thought to be most likely to be affected by changes in plasma proteins are those that are at least 80% protein bound (Maples et al., 2006, p. 217). Among the opioids, these include alfentanil (92%), buprenorphine (96%), fentanyl (84%), methadone (90%), and sufentanil (79% in neonates, 91–93% otherwise). Morphine is approximately 30% bound. The extent to which hydrocodone is bound to plasma proteins is not completely understood, although it is thought to be in the same range as other semisynthetic opioids, such as hydromorphone and oxycodone, approximately 19% to 45% (Vintage Pharmaceuticals, 2012). The clinical implications of these phenomena are not well understood, however, preterm infants and neonates may require lower doses of these drugs.

### Metabolism

Generally speaking, fetal drug metabolism is lower than in infants, and then increases in early childhood. The hepatic enzymes most commonly discussed in the context of opioid metabolism are CYP2D6 and CYP3A4, and the drugs most commonly affected are codeine, fentanyl, and hydrocodone. CYP2D6 is particularly important because it is known to show genetic polymorphism, with poor and extensive metabolizer groups (Leeder and Kearns 1997; May 1994). The drug most affected by variations in 2D6 activity is codeine, although about 4% of hydrocodone is metabolized to hydromorphone via this route. About 10% of a codeine dose is metabolized to morphine, however since poor metabolizers are not expected to generate any morphine and codeine is a prodrug, these individuals will not receive any analgesia from codeine (Yaksh and Wallace 2011). Extensive metabolizers, on the other hand, will produce more morphine from the same amount of codeine, which may result in significant toxicity. Codeine use by a nursing extensive-metabolizer mother has also resulted in death of the infant, and several children after tonsillectomy. A similar case in which a child who was a CYP2D6 poor metabolizer and was also receiving other drugs that interfered with metabolism of hydrocodone and its metabolites died has also been published.

The CYP3A4 isozyme is important in this context mainly in the biotransformation of alfentanil, fentanyl, sufentanil, and methadone (Yaksh and Wallace 2011). Persons with diminished enzyme activity or who are taking drugs that are themselves metabolized by this route or that inhibit this enzyme (e.g. macrolide antibiotics (erythromycin, clarithromycin, telithromycin)), azole antifungals (ketoconazole, itraconazole), or protease inhibitors, among others,

are at risk for toxicity due to increased levels of these opioids (see Table 45.1).

### Elimination

With the exception of methadone, the kidney is the primary route of elimination for the opioids. Methadone is eliminated via the gastrointestinal tract in bile, as well as in urine (Yaksh and Wallace, 2011). For children with decreased renal function, the doses of renally eliminated drugs are decreased (Nahata and Taketomo, 2011). In general, however, conditions and diseases that reduce blood flow to the liver (e.g. cirrhosis, congestive heart failure) reduce the clearance and increase oral bioavailability of drugs with high hepatic extraction. Among the opioids, the drugs that are highly hepatically extracted in adults include morphine, meperidine, fentanyl, sufentanil, but not alfentanil or remifentanil (Davis 2007; Tegeder et al., 1999).

### Nursing and lactation

As shown in Table 45.2, data on opioid use by nursing mothers is limited. In general, clinical decision-making rests on a foundation of assessing risk-to benefit ratio, and the expected duration of therapy.

One clinical scenario involving use of codeine by a nursing mother bears mention here. Although use by nursing mothers for short periods has been considered safe, use over a 2-week period by an ultrarapid metabolizer of has resulted in the death of a nursing infant (Koren et al., 2006).

### Language

Among the many challenges to providing high-quality pain management is making sure that patients, clinicians, and other caregivers, families, and regulatory officials are all speaking the same language. This is particularly important because the words and concepts involved are not only emotionally powerful, they have implications for clinicians' willingness to prescribe, and pharmacies' ability and willingness to fill prescriptions.

One of the challenges that complicates the treatment of pain and, particularly, the use of opioids is that the definitions (and consequently, understanding) of commonly used terms differ between medicine and psychology. For example, in the 2003 consensus definitions published by the American Society of Addiction Medicine, the American Pain Society, and the American Academy of Pain Medicine, addiction is defined as a primary, chronic, multifactorial,

**Table 45.1** Opioid metabolism

Opioid	Metabolic pathway	Major metabolites	Comments
Alfentanil	CYP3A4	NA	NA
Codeine	CYP2D6	Morphine	Approximately 10% of codeine dose is converted to morphine, however pharmacogenetic variation may result in varying clinical effects, from no production of morphine to higher conversion to morphine (resulting in toxicity or death)
Fentanyl	CYP3A4	NA	Fentanyl is available in various dosage forms (transdermal, transmucosal, buccal, sublingual, nasal), which are NOT bioequivalent.
Hydrocodone	CYP2D6	Hydromorphone	About 4% of dose is converted to hydromorphone
Hydromorphone	Glucuronidation	Hydromorphone-3-glucuronide	NA
Levorphanol	Glucuronidation	NA	NA
Meperidine	Hepatic	Normeperidine	Normeperidine is toxic, and may cause seizures. Accumulation may occur in persons with decreased renal function
Methadone	CYP3A4, CYP2D6	2-ethylidene-1, 5-dimethyl-3, 3-diphenylpyrrolidine (EDDP)	EDDP is inactive; Higher doses of methadone are associated with QT prolongation and potential for torsades de pointes
Morphine	Conjugation	Morphine-3-glucuronide, morphine-6-glucuronide	Metabolites accumulate with decreased renal function. M6G is analgesic, M3G may be proalgesic
Oxycodone	CYP2D6	Oxymorphone	Present only in small amounts
	Glucuronidation	Noroxycodone	Weaker than parent drug
Oxymorphone	Glucuronidation	Oxymorphone-6-glucuronide, 6-OH-oxymorphone	
Remifentanil	Ester hydrolysis	NA	NA
Sufentanil	N-dealkylation, O-demethylation via CYP3A4	NA	NA
Tapentadol	Conjugation, CYP2C9, CYP2C19, CYP2D6	Tapentadol-O-glucuronide	No active metabolites
Tramadol	CYP2D6, CYP3A4, conjugation	O-desmethyltramadol (M1)	M1 contributes to analgesic activity

Source: data from Yaksh and Wallace, 2011; Tegeder et al., 1999; Lundeberg and Roelofse, 2011; Tateishi et al., 1996; Sullivan and Due, 1973 and Eap et al., 2002. NA = not applicable.

**Table 45.2** Opioids in breast milk

Drug	Excreted into breast milk?	Clinically important?
Alfentanil	Yes	Limited human data—probably compatible
Codeine	Yes	Limited human data—potential toxicity
Fentanyl	Yes	Compatible
Hydrocodone	Not known	No human data—probably compatible
Hydromorphone	Yes	Limited human data - probably compatible
Levorphanol	Not known	No human data – probably compatible
Meperidine	Yes	Compatible
Methadone	Yes	Limited human data – probably compatible
Morphine	Yes	Limited human data—probably compatible
Oxycodone	Yes	Limited human data—probably compatible
Oxymorphone	Not known	No human data—probably compatible
Remifentanil	Not known	No human data—probably compatible
Sufentanil	Not known	No human data—probably compatible
Tapentadol	Not known	Manufacturer does not recommend use during breastfeeding
Tramadol	Yes	Limited human data—probably compatible

Compatible: either the drug is not excreted in clinically significant amounts into human breast milk or its use during lactation does not, or is not expected to, cause toxicity in a nursing infant.

No (limited) human data—probably compatible: there may or may not be human pregnancy experience, but the characteristics of the drug suggest that it does not represent a significant risk to the embryo/fetus. For example, other drugs in the same class or with similar mechanisms are compatible or the drug does not obtain significant systemic concentrations. Any animal reproduction data are not relevant.

neurobiological disease, characterized by impaired control over drug use, compulsive use, continued use despite harm, and craving. In the *Diagnostic and Statistical Manual of Mental Disorders, fourth edition, text revision* the term 'dependence' is used (American Psychiatric Association, 2000; Savage et al., 2003).

Drugs are often referred to as being addictive. Yet, while it is generally true that the reward experienced from a given drug is an important component of the decision to repeat use, there are also patient-specific factors that are important patient contributors to the development of addiction (Savage et al., 2003). In general, then, rather than blaming a drug or class of drugs for addiction, it is the combination of a physiologically and psychologically vulnerable person (and the degree of vulnerability is not constant), with a substance that produces reward that requires our attention. This idea also seems to help explain why some people prefer a class of drugs over others (alcohol versus nicotine versus opioids, and so on), as well as drugs within a class (codeine versus fentanyl, and so on).

Physical dependence is defined as a state of physiological adaptation in which a class-specific withdrawal syndrome occurs upon suddenly stopping use of a drug, quickly reducing the dose, use of an antagonist, or otherwise decreasing the blood level of drug (Savage et al., 2003). In other words, when sudden discontinuation of a drug is not recommended (for whatever reason), it can be viewed as dependence. Many drug classes fall into this category, not just opioids, including corticosteroids, anticonvulsants, and antihypertensives, among others.

Tolerance occurs when a specific effect of a drug decreases over time (Savage et al., 2003). Like physical dependence, tolerance is

currently understood to be a state of physiological adaptation, and can be a measure of safety. The heart of this definition is centred on the diminution of a specific effect. Thus, in referring to tolerance to an opioid, the assumption may be that the drug's analgesic effect has decreased, even if it is another effect of that drug. For example, in the opioids, tolerance to respiratory depression typically occurs fairly quickly, while tolerance to the constipating effects generally occurs slowly, if at all.

## Opioid analgesics

In general, opioids can be organized by the main type of opioid receptor the drug interacts with (Table 45.3), and by the drugs' general chemical structure (Table 45.4). The three main types of opioid receptor are mu, kappa, and delta (Yaksh and Wallace, 2011). While agonism at each of these receptors produces analgesia, most opioids currently available are mu agonists, and none of the opioids used in the US are delta agonists. Although the partial agonists and kappa agonists/mu antagonists were originally developed to be safer alternatives to the mu agonist drugs, the difference between these groups when given in equianalgesic doses is small and not thought to be clinically meaningful.

Opioids are categorized chemically as phenanthrenes, phenylpiperidines, or diphenylpropylamines (Yaksh and Wallace, 2011). The clinical implication of these differences is that, generally speaking, if a person cannot take a drug in one chemical group, such as morphine, it may be possible to cautiously use a drug from one of the other groups, such as methadone or fentanyl.

Table 45.3 Opioids by receptor activity

Mu agonists		Kappa agonist/Mu antagonists	Mu antagonists
Alfentanil	Opium	Buprenorphine (partial agonist)	Nalmefene
Codeine	Oxycodone	Butorphanol	Naloxone
Diamorphine (Heroin; not used clinically in the US)	Oxymorphone	Nalbuphine	Naltrexone
Fentanyl	Propoxyphene (withdrawn from the US market in 2010)	Pentazocine	
Hydrocodone	Remifentanil		
Hydromorphone	Sufentanil		
Levorphanol	Tapentadol		
Meperidine (Pethidine)	Tramadol		
Methadone			
Morphine			

Table 45.4 Opioid analgesics by chemical structure

Phenanthrenes	Phenylpiperidines	Diphenylpropylamines
Codeine	Alfentanil	Methadone
Hydrocodone	Fentanyl	Propoxyphene (withdrawn from the US market in 2010)
Levorphanol (a morphinan)	Meperidine	
Morphine	Remifentanil	
Oxycodone	Sufentanil	
Oxymorphone		

Since the focus of this chapter is to provide general clinical insight into opioid use for the treatment of pain, the discussion in this section will emphasize those opioids that are most commonly used in that setting (see Table 45.5). Alfentanil, remifentanil, and sufentanil are primarily used in surgical settings, and while nalmefene and naltrexone are opioid antagonists, they are used mainly in the treatment of alcohol dependence. As a result, the use of these drugs is beyond the scope of this effort.

Buprenorphine

Buprenorphine is a partial agonist at the mu opioid receptor, as well as an antagonist at the kappa and delta opioid receptors (Yaksh and Wallace, 2011). Its half-life in premature neonates after IV use is approximately 20 h (standard deviation 8), and it is metabolized to norbuprenorphine and other compounds. The role of buprenorphine in caring for children with pain is unclear, in part because of limited research on this topic, and in part because use of the agonist-antagonist drugs (buprenorphine, butorphanol, nalbuphine, and pentazocine) may precipitate withdrawal in persons who have been receiving mu agonist opioids. In two studies of children with postoperative pain after orthopaedic surgery, morphine and buprenorphine were each considered good or very good analgesics, with similar side effect profiles, despite the studies being considered to be low quality (World Health Organization, 2012). Transdermal buprenorphine has also

been studied in a small group of children with cancer-related pain (Ruggiero et al., 2013).

Codeine

Codeine is not recommended for use in children with persistent pain, due to well-documented problems with efficacy and safety (World Health Organization, 2012). This recommendation makes sense for children with other types of pain, as well. Specifically, codeine is a prodrug, and its analgesic activity is dependent on its conversion to morphine via CYP2D6. Persons with an absolute or functional lack of this will not experience analgesia from codeine or they may experience diminished analgesia relative to a given dose. Conversely, persons who are considered rapid or extensive metabolizers will experience more analgesia than would otherwise be expected. Toxicity and deaths have occurred in rapid metabolizers, as well as in children of nursing mothers who were taking codeine. Approximately 10% of a codeine dose is converted to morphine, and bioavailability is estimated as 30% to 60%. Thus, a 10 mg oral dose of codeine would be expected to provide approximately 0.3 to 0.6 mg of morphine. Given that genetic polymorphism with codeine has been well documented, there have been serious adverse events due to the use of therapeutic codeine doses, and morphine is readily available, the continued need to use codeine for analgesia is questionable at best (Ciszkowski et al., 2009; Kelly et al., 2012; Koren et al., 2006).

**Table 45.5** Dosing for commonly used opioids

Drug	Neonates	Infants	Children	Adolescents
<b>Buprenorphine:</b> <b>slow IV</b>			2–6 mcg/kg every 4–8 h (2–12 years of age)	3 mcg/kg every 6–8 h (≥13 years of age)
Fentanyl <sup>a</sup>				
Oral transmucosal			0.01 mg/kg/dose or 10–15 mcg/kg (oralet)	
<b>Intranasal</b>			1–2 mcg/kg	
IV bolus			0.001 mg/kg/dose or 0.5–1 mcg/kg every 1–2 h	
IV infusion			0.5 mcg/kg/h	
Hydrocodone			0.1–0.2 mg/kg every 4 h	
<b>Hydromorphone</b>				
Oral		40–80 mcg/kg every 4 h		
IV bolus		10–20 mcg/kg every 3–4 h		
IV infusion		3–5 mcg/kg/h		
<b>Methadone</b>				
Initial intravenous			0.05–0.1 mg/kg (up to 10 mg) every 3–4 h for 2–3 doses, then every 6–12 h	
Oral and subcutaneous			0.1 mg/kg (up to 10 mg) every 4 h for 2–3 doses, then every 6–12 h. Alternately, 0.7 mg/kg/day (up to 10 mg/dose) divided every 4–6 h	
<b>Morphine</b>				
Oral, immediate release		0.2–0.5 mg/kg every 3–4 h		
Oral, sustained release (older children & adolescents)			0.25–0.5 mg/kg every 8–12 h	
IV bolus	Preterm: 10–25 mcg/kg every 2–4 h	50–100 mcg/kg every 3 h		
	Full-term: 25–50 mcg/kg every 3–4 h			
IV infusion	Preterm: 0.01–0.03 mg/kg/h or 2–10 mcg/kg/h	15–30 mcg/kg/h		
	Full-term: 5–20 mcg/kg/h			
<b>Oxycodone</b>			0.05–0.2 mg/kg every 4–6 h	

<sup>a</sup>Fentanyl: transdermal, transmucosal, intranasal use is not for use in outpatient or unobserved settings, or in opioid-naïve patients.

### Diamorphine (diacetylmorphine, heroin)

Although not available for clinical use in the US, diamorphine is used in the UK in children for a variety of painful conditions and for pain at the end of life (Hewitt et al., 2008), intranasal use in emergency settings (Finn and Harris, 2010; Hadley et al., 2010), and sickle cell pain (Telfer et al., 2009).

Metabolism to 3- and 6-monoacetylmorphine and then to morphine occurs quickly when diamorphine is given by mouth. In contrast, administration by injection or other routes that avoid the first-pass effect allows the drug to cross the blood–brain barrier more rapidly than morphine or other, less fat-soluble opioids. It is not known if diamorphine offers any clinical advantage in terms of

its ability to produce analgesia over drugs that are even more lipid-soluble, such as methadone or fentanyl, when given by the same route.

### Fentanyl

Fentanyl is approximately 100 times more potent than morphine on a milligram-to-milligram basis (Yaksh and Wallace, 2011). It is also lipophilic, which results in relatively rapid onset of action (except when used transdermally). Although fentanyl is metabolized to inactive products via CYP3A4, this process is decreased by a wide variety of drugs. These drugs include, but are not limited to amiodarone, aprepitant, the azole antifungals

(i.e. fluconazole, itraconazole, ketoconazole), calcium channel blockers (e.g. diltiazem, verapamil), macrolide antibiotics (clarithromycin, erythromycin, telithromycin), nefazodone, and protease inhibitors (e.g. fosamprenavir, ritonavir, indinavir, nelfinavir, saquinavir). The result of this interaction has included fatalities due to respiratory depression. As a result, close monitoring (including dose reduction of fentanyl as indicated) is absolutely required, particularly when using fentanyl with drugs that inhibit the CYP3A4 pathway.

Fentanyl is also of interest because it is one of the only opioids that is available for transdermal use, along with buprenorphine, or intranasal use (diamorphine is used intranasally in the UK) and fentanyl is the only opioid available for transmucosal use. Transdermal fentanyl should not be used in people who are opioid-naïve. Additionally, although there are several transmucosal and one intranasal fentanyl products available, they are not bioequivalent to each other, and cannot be interchanged without titrating. Further, using these products in children is a challenge because the doses are chosen based on adult opioid dosing, although Borland et al. (2011) assessed the use of intranasal fentanyl in 50 mcg/ml or 300 mcg/ml concentrations using a calibrated delivery device to provide 1.5 mcg/kg (up to 0.2 ml per nostril) in 189 children aged 3 to 15 years who presented to an Australian emergency department with clinically deformed closed long bone fractures. These authors concluded that these concentrations were clinically equivalent in their provision of analgesia, and that the lower concentration was reasonable for children weighing less than 50 kg.

### Hydrocodone

Most hydrocodone is used in the US, although it is also available (to a much smaller degree) in other countries, including Argentina, Belgium, Canada, Columbia, Germany, Guatemala, and Switzerland (International Narcotics Control Board, 2013). Bioavailability information is not available, and limited data suggest that hydrocodone is roughly equipotent to morphine on a milligram to milligram basis. Approximately 4% of a hydrocodone dose is transformed to hydromorphone via CYP2D6. Since CYP2D6 is the same pathway that biotransforms codeine, similar safety and efficacy problems are possible.

In the US, hydrocodone is not available for parenteral use, and it is always used in combination with other drugs, most typically acetaminophen (paracetamol). While the usual initial dose in opioid-naïve children who weigh less than 50 kg is 0.1 to 0.2 mg/kg every 3 to 4 h, and 5 to 10 mg every 3 to 4 h in children who weight at least 50 kg, maximum dosing is a function of other drugs (i.e. acetaminophen) present (Lexicomp, 2013a).

### Hydromorphone

Hydromorphone is approximately five times as potent than morphine on a milligram to milligram basis (Yaksh and Wallace, 2011). Its oral bioavailability is approximately 20% to 60% (Lexicomp, 2013b) by mouth and approximately 51% intranasally, although, in one study, the interindividual variability was 59%. Metabolism is via glucuronidation to inactive products, which are eliminated in the urine. Usual initial doses for infants older than 6 months of age who weigh more than 10 kg are 0.03 to 0.06 mg/kg given by mouth every 3 to 4 h as needed, 0.01 mg/kg intravenously, given every 3 to 6 h, or 0.003 to 0.005 mg/kg/h by continuous IV infusion (Friedrichsdorf and Kang 2007; Lexicomp 2013b; Zernikow et al.,

2009). In older children and adolescents who weigh less than 50 kg, oral doses of 0.03 to 0.08 mg/kg every 3 to 4 h, 0.015 mg/kg intravenously every 3 to 6 h, or 0.003 to 0.005 mg/kg/h up to a maximum of 0.2 mg/h by continuous IV infusion.

### Meperidine (British approved name: pethidine)

Meperidine is not recommended for use as an analgesic, due to its active and toxic metabolite, normeperidine, which can accumulate (elimination half-life in neonates is 30–85 h) and cause seizures. Because of its poor risk:benefit profile, meperidine has been removed from many formularies in the US. Meperidine is about one-tenth as potent as morphine and it is about 30% bioavailable when given by mouth (Lexicomp, 2013c). If alternatives to meperidine are not available or are contraindicated, usual meperidine dosing in children is 1 to 1.5 mg/kg every 3 to 4 h by mouth or parenterally. By continuous IV infusion, a loading dose of 0.5 to 1 mg/kg can be given, followed by 0.3 mg/kg/h initially, with titration to effect up to 0.5 to 0.7 mg/kg/h.

### Methadone

Methadone is a potent opioid that is challenging to use, due to its long elimination half-life of approximately 19 h (range 4–62), and because the elimination half-life is substantially longer than the duration of analgesia, which is 6 to 8 h initially (Lexicomp, 2013d). Methadone is approximately 80% bioavailable and is metabolized to an inactive product via CYP3A4 and CYP2D6, and eliminated in the urine (approximately 10% of unchanged drug) and faeces. It also has the potential to cause cardiac arrhythmias. Choice of a dose must be done carefully, and is best viewed as a process, rather than a single event, since the dose and dosing interval will likely change over the first few days of therapy due to accumulation (Weschules and Bain, 2008). It is also critically important to recognize that equianalgesic conversion involving methadone is not a linear calculation. For example, in contrast to the idea that hydromorphone is about five times as potent as morphine or that fentanyl is about 100 times as potent as morphine, the ratio of methadone to morphine varies based in part on how much morphine the person was receiving. There are several methods available to estimate methadone doses, and while each differs slightly from each other, the hallmark is that the expected dose of methadone decreases as the dose of morphine increases.

### Morphine

Morphine is the prototypical opioid and is generally the opioid of first choice, due to its effectiveness, extensive clinical experience using it, and low cost. When given by mouth, it is approximately 30% bioavailable, and is metabolized to morphine-3- and morphine-6-glucuronides (Lexicomp, 2013e; Yaksh and Wallace, 2011). While morphine-3-glucuronide is not an analgesic, some evidence suggests that it may be proalgesic. In contrast, morphine-6-glucuronide has analgesic activity. Both compounds can accumulate in people with decreased renal function. The elimination half-life of morphine generally decreases from 10 to 20 h in preterm infants to 1 to 2 h in preschool-aged children.

### Opium

Although used primarily as an antidiarrheal, opium can also be used as an analgesic. It contains several alkaloids, including morphine (10% of opium) and codeine (0.5% of opium) (Yaksh and

Wallace, 2011). It is important to note that opium is available as a tincture (10 mg morphine/ml), as well as in paregoric (2 mg morphine/5 ml). The difference between these products is critical, since opium tincture contains 25 times more morphine than paregoric. Paediatric dosing of paregoric is 0.25–0.50 ml/kg one to four times a day (Lexicomp, 2013f).

### Oxycodone

The main differences between oxycodone and morphine have to do with metabolism and bioavailability. Oxycodone is metabolized via CYP2D6 to oxymorphone (which is present only in small amounts) and is glucuronidated to noroxycodone (Yaksh and Wallace, 2011). The relative lack of clinically important active metabolites makes oxycodone a reasonable choice for patients with diminished renal function. Oxycodone is approximately 80% bioavailable.

### Tapentadol

Metabolism of tapentadol is via conjugation, as well as CYP2C9, CYP2C19, and CYP2D6 to inactive products. In terms of efficacy, tapentadol is broadly considered to be similar to tramadol, although tapentadol has less effect on serotonin reuptake inhibition than tramadol (Yaksh and Wallace, 2011). No articles on tapentadol and children were identified in a literature search of PubMed-indexed journals. According to the professional prescribing information, the safety and effectiveness of tapentadol has not been established in patients less than 18 years of age (Janssen Pharmaceuticals, 2012).

### Tramadol

Tramadol is not recommended for treatment of persistent pain in medically ill children, due to lack of evidence and lack of regulatory approval in this population (World Health Organization, 2012). This recommendation likely applies to children with other kinds of pain as well. Although tramadol is considered a codeine analogue, it is structurally dissimilar from the other phenanthrene opioids, thus, it may be a reasonable choice in people who cannot take other opioids (Yaksh and Wallace, 2011).

## Side effects and adverse events

While respiratory depression is commonly considered the most concerning potential side effect of the opioids, other side effects closely associated with the opioids include nausea and vomiting, itching, urinary retention, dizziness, and sedation (see Table 45.6). Since adverse events considered broadly are simply things that are undesirable at the time and from the perspective being considered, it also makes sense to think about these occurrences more broadly. One example of this is a commentary by Chorney et al. (2010), in which the authors consider the implications of viewing pain as an adverse event itself.

Pain management aside for a moment, the general approach to addressing adverse events and side effects consists of prevention when possible, followed by decreasing the dose (or administration frequency), using a different drug in place of the implicated medication, or as a last resort, continuing with the medication associated with the adverse event and adding another drug to treat the unwanted event or symptom. An example of the latter situation is to use low doses of a central nervous system stimulant in a person whose pain is well controlled, but who is sedated. A variety of treatment methods have been used, including opioid rotation, use of

different routes of administration, and use of drugs with different mechanisms of action to help decrease the patient's opioid requirement. Although we are moving into a time in which comparative effectiveness studies are considered increasingly important, much of the published biomedical literature relies heavily on placebo-controlled trials. As a result, although randomized, controlled trials comparing opioids are not very common, clinical practice often includes trying another drug in a class if the patient doesn't tolerate the first drug chosen.

### Nausea and vomiting

Nausea and vomiting are among the most undesirable adverse effects of clinical anaesthesia, from the points of view of patients as well as clinicians (Macario et al., 1999a, 1999b). Despite the importance of avoiding these adverse effects, prevention and treatment have remained challenging, in part due to varying mechanisms of action. While opioids are often implicated as causes due to their effects on the central nervous system, gastrointestinal tract, and other physiological systems, other drugs and pain also cause nausea. Depending on the underlying cause, treatment typically consists of a variety of drugs, including phenothiazines, haloperidol, and the 5-HT<sub>3</sub> receptor antagonists, of which dolasetron, ondansetron, and palonosetron have been approved by the US Food & Drug Administration for prevention of postoperative nausea and vomiting (Hardy et al., 2002; Schug et al., 1992; Sussman et al., 1999). Antihistamines, transdermal scopolamine, and metoclopramide have also been used.

### Itching

Although commonly attributed to histamine release (and treated that way), the pathophysiological mechanisms underlying opioid-related itching are hypothesized multiple pathways to involve spinal opioid receptors, disinhibition of specific neurons, or central serotonin (5-HT<sub>3</sub>) receptors (McNicol, 2007; Schmelz, 2002; Schug et al., 1992). It is also important to recognize that itching may be caused or aggravated by other diseases and conditions, including cholestatic liver disease, as well as skin conditions, like dry skin or eczema, although the latter are typically localized versus generalized.

Treatment of itching is often focused on H<sub>1</sub>-receptor antagonists, although itching also occurs with fentanyl and sufentanil, which do not cause histamine release (Schug et al., 1992). If antihistamines are used, there is potential for drug interactions to enhance sedation. In these individuals, more frequent monitoring for respiratory function will be important. Nalbuphine has also been used, but this drug is an antagonist at the mu opioid receptor, so there is the potential for analgesia to be reversed or withdrawal to be induced (Yaksh and Wallace, 2011). In one recent review, Miller and Hagemann (2011) evaluated the published biomedical literature on the use of naloxone, naltrexone, or methylnaltrexone for management of opioid-induced itching. These authors concluded that IV doses of 0.25 to 1 mcg/kg/h of naloxone is optimal for reversal of itching without also affecting analgesia. Yet, since most people in an ambulatory setting don't have percutaneous access, optimal treatment of itching in community-based patients will likely centre on opioid rotation.

### Respiratory depression/sedation

Opioids produce a dose-related decrease on all phases of respiration (Yaksh and Wallace, 2011). It is a more common occurrence in individuals who are opioid-naïve or -inexperienced, as well as persons

**Table 45.6** Selected drugs and dosing for opioid-related side effects

Side effect and drugs	Neonates	Infants	Children	Adolescents
<b>Nausea</b>				
Diphenhydramine, by mouth or intravenously			0.5–1 mg/kg every 4–6 h as needed	
Lorazepam, by mouth or intravenously			0.02–0.04 mg/kg (up to 2 mg) every 6 h	
Ondansetron, by mouth or intravenously			0.15 mg/kg (up to 8 mg) 1–4 times a day	
Prochlorperazine, by mouth or rectally			0.1–0.15 mg/kg every 6–8 h	
Promethazine, by mouth or intravenously			0.25–0.5 mg/kg every 4–6 h as needed	
<b>Respiratory depression/sedation</b>				
Naloxone			0.02 mg every 30–60 secs until improvement (may need to repeat)	
Itching: diphenhydramine, by mouth or intravenously			0.5–1 mg/kg every 6–8 h	
Nalbuphine, intravenously <sup>a</sup>			0.01–0.02 mg/kg every 6–8 h as needed	
Naloxone, by infusion			0.25–1 mcg/kg/h	
Constipation: docusate (1–4 divided doses by mouth per day)				
<3 years of age			10–40 mg	
3–6 years of age			20–60 mg	
6–12 years of age			40–150 mg	
>12 years of age			50–400 mg	
Senna, by mouth			10–20 mg/kg/dose 1–2 times a day	
Bisacodyl tablets, by mouth			5–10 mg (must be able to swallow a tablet whole)	
Suppository, rectally			5 mg (<2 years of age), 10 mg (>2 years of age)	
Magnesium citrate, by mouth: <6 years of age			2–4 ml/kg a day (in single or divided doses)	
6–12 years of age			100–150 ml once a day	
12 years of age or older				150–300 ml by mouth once a day
Magnesium hydroxide, by mouth: <2 years of age			0.5 ml once a day	
2–5 years of age			5–15 ml once a day	
6–12 years of age			5–30 ml once a day	
12 years of age or older				30–60 ml once a day
Mineral oil: 5–11 years of age, by mouth			5–15 ml once a day	
12 years of age or older, by mouth				15–45 ml once a day
2–11 years of age, rectally			30–60 ml	
12 years of age or older, rectally				60–150 ml retention enema
Glycerine: under 6 years of age, rectal or enema			1 infant suppository, one or two times, or 2–5 ml as an enema	
6 years of age or older, rectal or enema			1 adult suppository, one or two times, or 5–15 ml as an enema	
Lactulose, by mouth			7.5 ml once a day after breakfast	
Polyethylene glycol, by mouth (in 4–8 ounces of fluid)			8.5–17 grams (0.5–1 capful or packet) one to three times a day	

(Continued)

Table 45.6 (Continued)

Side effect and drugs	Neonates	Infants	Children	Adolescents
Polyethylene glycol–electrolyte solution, by mouth			25–40 ml/kg/h until constipation is relieved	
Methylnaltrexone, <sup>b</sup> subcutaneously or enterally			0.15 mg/kg once every other day to every day	
Naloxone, by mouth <sup>a</sup>			2–12 mg three times a day	

Prevention of constipation should be with a stool softener/laxative combination, such as senna with docusate.

<sup>a</sup>Naloxone and nalbuphine must be titrated carefully to avoid reversing opioid analgesia and precipitating withdrawal symptoms.

<sup>b</sup>Methylnaltrexone dosing is based on a case report of one 4-year-old patient with epidermolysis bullosa (Lee and Mooney, 2012; Facts & Comparisons). Safety and efficacy have not been evaluated for labelling purposes in children. The dose of 0.15 mg/kg is the usual adult dose for persons weighing less than 38 kg. For adults who weigh 38–less than 62 kg, the dose is 8 mg, and for persons who weigh 62–114 kg, the dose is 12 mg.

who have limited respiratory function, or conditions like asthma. Tolerance to this effect generally happens reasonably quickly.

Sedation is a more useful measure of the risk of respiratory depression than respiratory rate alone, since sedation occurs before the person's breathing is depressed. A variety of sedation scales are used in clinical practice; these typically include a measure of how sedated the person is, as well as how easily the person is aroused. The level of sedation may be useful, along with the trend. Treatment for respiratory depression focuses on use of naloxone and, if needed, oxygen. If naloxone is used, however, it should be given slowly to avoid antagonizing analgesia. Additionally, since the half-life of naloxone is short, the dose will likely need to be repeated (Yaksh and Wallace, 2011).

## Constipation

Although constipation is common in persons who are treated with opioids, tolerance to this effect develops only slowly, if at all. As a result, prophylactic use of laxatives—typically a stimulant such as senna with a stool softener—is considered first-line therapy. In practice, however, as well as in persons at the end of life, either no treatment or prevention, or use of only a stool softener remains relatively common. In one study of paediatric and adult hospice patients, for example, approximately 26% of persons were not prescribed any laxatives, and 4% were prescribed only a stool softener (Strassels et al., 2010). The problem with using just a stool softener is that it doesn't address the decreased gastrointestinal motion that occurs with opioid use. Additionally, as gastrointestinal transit time is increased, there is more time for water to be absorbed, in addition to drying effects of the opioids. Other options include drugs such as methylnaltrexone, alvimopan, nalbuphine, and naloxone. Alvimopan and methylnaltrexone are peripheral mu-opioid receptor antagonists. The concept underlying these drugs is that antagonism of peripheral opioid receptors is useful to treat opioid-induced side effects, like constipation, without affecting centrally-mediated analgesia. Although no English-language reports of the use of alvimopan in children with opioid-induced constipation have been published in PubMed-indexed journals as of this writing (January 2013), two case reports of the use of methylnaltrexone in children with opioid-induced constipation have been published (Kissling et al., 2012; Lee and Mooney, 2012). In each of these reports, 0.15 mg/kg was used. It is worth noting that, in a 2008 Cochrane review conducted on the use of mu-opioid antagonists for opioid-induced bowel dysfunction, the authors concluded that the evidence at the

time supported neither a class effect of the opioid antagonists, nor was there evidence of superiority of one drug over another (McNicol et al., 2008). Similarly, they found that neither safety nor efficacy of naloxone or nalbuphine was supported for use in patients with postoperative ileus or opioid-induced constipation.

## Hyperalgesia

Hyperalgesia refers to an increased response to a painful stimulus at either a normal or increased threshold (IASP 2011). In contrast, the term opioid-induced hyperalgesia (OIH) is broadly defined as patients becoming more sensitive to pain due specifically to the use of opioids (Compton et al., 2001; Mao, 2008; McNicol, 2007; Werner, 2012). There are significant gaps in understanding the mechanisms underlying OIH, as well as the clinical relevance of this phenomenon (Chapman et al., 2010; Werner, 2012).

The pathophysiology of OIH is incompletely understood, and it remains important to emphasize that decreased analgesia from opioids may reflect hyperalgesia, tolerance, worsening disease, or a combination of these phenomena which remains a puzzle that has not yet been solved (Ballantyne and Shin, 2008).

Having said that, the science underlying increases in pain sensitivity is growing rapidly. Specifically, hyperalgesia appears to occur in a wide variety of clinical settings and patient populations, including persons on maintenance opioid use and in withdrawal of opioid, as well as persons receiving methadone for opioid maintenance and surgical patients (Angst and Clark, 2006). There also appears to be variation in the type of increased painful response to different stimulation. For example, in persons being maintained on methadone, hyperalgesia was found to occur to cold, but to a lesser degree for electrical stimuli and not to mechanical pain. In persons who underwent surgery, the development of hyperalgesia appeared to be associated with receiving higher opioid doses, although this finding has not been consistent, nor is it necessarily easy to separate hyperalgesia from tolerance.

Remifentanyl, a potent opioid that is used primarily in surgical settings, is known to produce a post-infusion hyperalgesia. In a recent study of ten patients, persons who received remifentanyl and propranolol did not experience mechanical hyperalgesia, while individuals who received remifentanyl and placebo did have hyperalgesia (Chu et al., 2012a). Although the sample size for this study was very small, these authors concluded that propranolol may be useful to prevent hyperalgesia in persons treated with opioids.

In a separate publication, in a study of adults with chronic non-radicular low back pain who used sustained-release morphine, these authors have also demonstrated that tolerance can occur independently from OIH (Chu et al., 2012b).

Another recent study provides some insight into the molecular link between increased pain and opioids. In the *OPRM1* gene (which codes for the mu opioid receptor) higher levels of DNA methylation was associated with chronic opioid use in former opioid addicts being treated with methadone as replacement compared with matched healthy controls, (Doehring et al., 2013; Stone and Szyf, 2013). Although this change was not associated with coding for the mu opioid receptor, it was associated with increased chronic pain.

Risk factors for development of OIH are not yet well understood. In the 2010 research guideline on future research pertaining to the use of opioids for chronic non-cancer pain, the authors note that several critical topics have yet to be addressed, including the epidemiology of OIH, the likelihood of developing OIH as a function of clinical and demographic characteristics, the interaction between hyperalgesia and acute pain, and, notably, dose and duration of therapy. While facets of a patient's clinical presentation such as dose, duration of therapy, and quantitative sensory testing may be helpful to identify patients at increased risk for altered pain sensitivity, these factors are neither sensitive nor specific.

Treatment regimens for suspected OIH generally include options such as dose increase (to rule out tolerance), dose decrease, adding (or changing to) drugs that are antagonists at the N-methyl D-aspartate receptor (ketamine and methadone, respectively), clonidine, and dexmedetomidine. Buprenorphine may be useful, and multimodal analgesia also has potential, as a function of the opioid-sparing effect of these regimens. There are not many studies of treatment for hyperalgesia in children, thus dosing information is similarly limited.

In one case report of suspected OIH in a medically complex infant with gastroschisis, morphine and fentanyl were used for postoperative pain initially. In the face of increasing pain and irritability, a variety of pharmacological approaches were tried with success after 46 days, including addition of IV clonidine at 0.33–0.45 mcg/kg/h, switching the opioid to hydromorphone, introduction of IV ketamine at 0.1 mg/kg/h, and IV dexmedetomidine at 0.7 mcg/kg/h in place of clonidine (Hallett and Chalkiadis, 2012). Use of dexmedetomidine (dose range 0.2–0.7 mcg/kg/h) in a case series of 11 patients, including a 9-year-old male and two adolescents, has also been reported (Belgrade and Hall, 2010). More than half of the individuals reported in this series experienced substantial decreases in their opioid requirements after use of dexmedetomidine, none had clinically significant withdrawal symptoms, and pain intensity was stable or decreased for most patients.

## Efforts to improve safe access to opioids

There is ample evidence in the biomedical literature documenting the need for improved care for people with pain. At the same time, there is significant concern about the potential for opioids to be misused, abused, or diverted, resulting in adverse events and deaths. In 2011, the US Centers for Disease Control and Prevention estimated that the rate of deaths related to prescription analgesic overdose had increased by more than threefold since 1990, that

the number of these events was greater than that of motor vehicle deaths and larger than deaths attributed to cocaine and heroin overdoses. (Alexander et al., 2012; Centers for Disease Control and Prevention, 2011). While these data do not tell us important information such as where the drugs were obtained, whether the overdose was intentional or accidental, and if the event was due to use of one drug or multiple medications, it is clear that there is a serious problem. As a result, there are a variety of efforts underway to better educate healthcare providers, and to monitor use of controlled medications.

## Prescription monitoring programmes (PMP)

As of October, 2012, 41 US states have an operational PMP in place and an additional ten (including the District of Columbia and Guam) have enacted legislation, but the programme has not yet begun operating (Alliance of States with Prescription Monitoring Programs, 2012). These programmes generally collect information about the patient, the drug and amount being prescribed, the date the prescription was written and the date it was filled, and the pharmacy that filled the prescription. States differ in terms of what data are collected, what time lag between filling the prescription and submitting the information is allowed, and who is responsible for maintaining the dataset (In Texas, it is the Department of Public Safety, in other states, the Board of Pharmacy or other groups are responsible.) Yet, despite the prevalence of PMPs, it remains unclear how to best use this information to achieve optimally safe and effective pain management. Here are a few challenges and opportunities that remain for healthcare providers and health policy decision-makers before the promise of these data can be fully realized.

Much of the PMP-related literature and discussions focus on drug abuse, often using prescriber- or pharmacy-shopping as markers of inappropriate use of controlled substances. Yet, we don't know the right number of prescribers or pharmacies, the right time period to consider, or whether there is even a right number. For example, in a literature search of 'prescription monitoring program' AND 'opioid', time intervals used to define either doctor- or pharmacy shopping included zero (concurrent use of opioids or controlled substances from different prescribers; Ives et al., 2006), 6 months (Pradel et al., 2009), 30 days (prescription for the same medication from at least two practitioners filled by at least two pharmacies; Gilson et al., 2012; Wilsey et al., 2010), and 1 year (Baehren et al., 2010; Hall et al., 2008; Wilsey et al., 2011), although one consensus statement published in 2004 defined use of multiple prescribers as at least six prescribers over a 1-year period (Parente et al., 2004). In a recent analysis, Wilsey and colleagues used California PMP data to assess differences between people who used only one prescriber compared to individuals who used two to five prescribers over a 1-year period (Wilsey et al., 2010). These investigators found that people who used two to five prescribers were not different in terms of male sex, younger age, or location in larger geographic areas—factors thought to be associated with drug abuse.

To make things more complex, the allure of considering data in isolation is powerful, even though looking at a broader picture often provides insight that a simple view cannot. As H. L. Mencken (1917) said, 'There is always an easy solution to every human problem—neat, plausible, and wrong'. One example of this idea is that the period of time in which the prescriptions were filled may help

explain the observed numbers of prescribers and pharmacies. The longer that period, the more likely it is that multiple explanations for a patient's behaviour are important in understanding their medication use.

Along these lines, it is worth looking beyond the absolute number of prescribers and pharmacies from multiple prescribers or pharmacies to ask why people might get prescriptions, aside from potential abuse, misuse, or diversion. A single medical practice may include several people writing prescriptions, individuals may see other prescribers when their usual caregiver is not available, and people who are medically complex may have good reasons for obtaining controlled substances from multiple prescribers. Similarly, there may be important differences between groups of people who use prescription opioids non-medically, but for pain only as opposed to persons who obtain these drugs for nonmedical and non-pain use (Zacny and Lichtor, 2008). The count of pharmacies is also suspect. People may choose to go to different pharmacies for any number of reasons, and this is not necessarily a problem. It is common for pharmacies to offer financial incentives to people who transfer prescriptions, convenience of location is often important, and pharmacies don't always carry (or can't get) the specific medication the patient is looking for in the needed timeframe. Despite the potential to limit legitimate access to pain management services, in November 2011, the pharmacy chain CVS/Caremark (2011) announced a new policy to refuse to fill prescriptions for Schedule II controlled medications from some prescribers in Florida. Pharmacies' decisions to not carry certain medications or blanket refusals to fill prescriptions are likely to result in unnecessary suffering among the vast majority of pain patients who use their medications appropriately and to increase the barriers to needed health care these people must face.

Data quality is another issue that needs close attention (Strassels, 2012). The information that comes out of PMPs is only as good as the data that are put in. These data are generally input at busy pharmacies, patient names and birthdates may be the same, and prescribers often have multiple offices. Data may also be missing, misspelled, or otherwise incorrect. Furthermore, as a result, interpretation of these data may be challenging, and prescribers and pharmacists must not jump to conclusions and inadvertently contribute to difficulties in access to appropriate pain management services.

Assessment and identification of prescription drug abuse or misuse in paediatric populations presents challenges in addition to those that apply to adults. For example, while many discussions of PMPs and prescription drug abuse, misuse, and diversion focus on opioids, we must recognize that these drugs and prescribing rates do not tell the whole story. Individuals being treated for chronic pain are often on multiple psychoactive medications, such as muscle relaxants, benzodiazepines, and antidepressants, and that these combinations may have their own problems. For example, in a 2006 editorial on whether being on chronic opioid therapy should be a contraindication to driving, Zacny (2006) counsels caution, since we don't know to what extent different combinations of drugs result in what outcomes.

Although much of the discussion surrounding PMPs emphasizes their use as tools for drug enforcement, they can also be used to better understand patient outcomes, including estimating the present and future needs for pain management services based on incidence

and prevalence trajectories, and use of geospatial tools to better understand access issues. PMP data are also useful to better understand and improve the safety of opioid use, whether these drugs are used alone or in combination with other analgesics. Last, it may be possible to link these data to other population-level resources to better understand the results and consequences of using pain management resources, including unintended consequences of public policy.

PMPs and other data collection efforts are used elsewhere as well. While systems that are used to collect information about prescribed drugs are common in many countries, allowing surveillance of opioid prescribing and dispensing, the literature on this topic published in the last 5 years pertains primarily to Australia, Canada, and France.

In one example of PMP use in New South Wales, Australia, with other large datasets to establish drug source and reason for use, the mortality associated with overdoses of methadone or buprenorphine was estimated (Bell et al., 2009). In this analysis, investigators found that approximately five times as many people were treated with methadone than with buprenorphine for opioid dependence. Of the individuals who died, 60 were on methadone and seven were using buprenorphine. Half of the methadone patients and none of the buprenorphine patients who died were in treatment. The authors concluded that the risk of overdose death was lower in buprenorphine patients than in methadone patients, although the confidence interval for the relative rate was wide (relative risk 4.25, 95% confidence interval 1.03–17.54). The authors also noted that use of more than one drug was common among the persons treated with methadone, particularly of heroin, benzodiazepine, and antidepressants.

Among the analyses exploring opioid use in Canada, one study found that interprovincial disparities in the numbers and types of opioids prescribed were common during 2005 to 2010 (Fischer et al., 2011). The authors also found that increases in the use of strong opioids was an important driver of this result, although this paper focused on the drug dispensing and not specific outcomes as a result of dispensing.

Building on these results, an analysis was carried out to estimate the relation between use of prescription opioids and mortality in British Columbia and Ontario from 2005 to 2009 (Fischer et al., 2013). These authors found strong correlations between the use of fentanyl, hydromorphone, morphine, and oxycodone and drug-related mortality, although they also noted that non-retail dispensing was not included here, nor were they able to assess concomitant use of drugs that may have contributed to death, such as non-opioid medications or alcohol.

In France, analyses were conducted to estimate the diversion of opioids relative to benzodiazepines and to quantify the effect of a PMP on doctor-shopping for high-dose buprenorphine therapy from 2000 to 2004. In the first paper, the authors found that, although benzodiazepines were dispensed more frequently than opioids, abuse, and diversion were observed mainly in association with opioid maintenance therapy, morphine, and benzodiazepines, and less so to non-morphine opioids (Pauly et al., 2012). In the second analyses, the authors estimated that, from 2004 to 2005, the prescription drug database contributed to a decrease in doctor-shopping, without adversely affecting the number of patients treated or the total prescribed doses (Pradel et al., 2009).

### Case example

Jackson is a 13-year-old, 50 kg boy with sickle cell disease. He usually manages his pain at home with oxycodone 5 mg as needed. He has not been hospitalized in 2 years. Over the last 2 days Jackson has had persistent pain in his abdomen and legs which has not improved despite taking oxycodone every 3 to 4 h. His mother brings him to the emergency department.

At triage in the emergency department Jackson reports his pain score as 10 out of 10 on a visual analogue scale. He is given fentanyl 50 mcg intranasally and brought immediately back to a patient care room.

He is then evaluated by the physician and 30 min after the fentanyl his pain score is a 9. An IV line is started and he is given 5 mg of morphine IV as well as 30 mg of ketorolac and IV fluids. His pain score remains a 9 and 40 min later he is given another 5 mg dose of morphine. This does not result in improvement and he is transferred to the inpatient unit.

On the inpatient floor he reports a pain score of 9. He also complains of itching and requests that he be switched to hydromorphone as that did not cause him as much itching during his last hospitalization.

He is placed on a hydromorphone via patient-controlled analgesia with a 0.2 mg per hour continuous infusion and a 0.1 mg bolus every 6 min as needed. He is also placed on IV fluids and senna. He is encouraged to use an incentive spirometer.

Over the next 24 h Jackson continues to have severe pain. His continuous infusion is increased to 0.3 mg per hour.

By day 3 of hospitalization he reports his pain is now a 5. On this day his continuous infusion is stopped and he is placed on extended release oxycodone (10 mg every 12 h). He remains on a bolus only PCA for 24 more hours and then this is discontinued. He is sent home on the extended release oxycodone as well as 5 mg of immediate-release oxycodone to be used as needed. He is told to remain on the senna as long as he is taking the oxycodone. A follow-up appointment is made for 5 days after discharge.

## CHAPTER 46

---

# Interventional pain management techniques for chronic pain

Navil F. Sethna, Pradeep Dinakar,  
and Karen R. Boretsky

### Summary

As part of multidisciplinary management of paediatric chronic pain, interventional pain management techniques can play an important role when pain is unrelieved by conventional treatment modalities. Many procedures and indications are extrapolated from adult studies, and evidence for long-term efficacy in paediatric populations is limited. Interventions range from injection techniques with local anaesthetic and/or corticosteroids to neuraxial blockade with implanted catheters. Paediatric case series have reported benefit in selected patients with complex regional pain syndrome and cancer-related pain.

### Introduction

Significant improvement in our understanding of paediatric pain neurobiology and its adverse effects has increased awareness for the need for early analgesic intervention to mitigate the acute and long-term consequences of pain. As part of multidisciplinary management of paediatric chronic pain, interventional pain management (IPM) techniques play an important role when pain is unrelieved by conventional treatment modalities. Although these techniques have long been the mainstay of adult chronic pain management, the lack of outcome data in paediatric populations has limited its utility. As with adults, paediatric chronic pain requires multidisciplinary management, combining psychosocial support and pharmacotherapy, and including IPM when required to provide the best possible options for managing pain and improving quality of life.

Several textbooks and manuals have been published describing detailed applied anatomy and approaches and techniques of IPM in adults (Peng and Tumber, 2008) but only a few case reports and case series are described in children. The experience with application of these blockades in paediatric population is very limited and citation of references in this chapter refers to adult literature unless specified for children. It is not the intention of this chapter to duplicate these technical details and readers are referred to adult

standard textbooks for detailed technical information (Cousins et al., 2009; Fishman et al., 2010; Prithvi Raj, 2008). This chapter focuses on commonly useful procedures that are increasingly used in paediatric patients with chronic pain syndromes. Physicians who perform IPM techniques in children should be familiar with differences in developmental anatomy and pharmacology and trained and experienced in regional nerve blocks in adults and children. As a general principle all IPM procedures for chronic pain disorders must be performed as adjunct to multimodal therapies in the setting of interdisciplinary programme.

### General patient considerations

Interventional pain management techniques are widely used in the paediatric population in acute postoperative pain, but also have a role in chronic paediatric pain management. Patients and families should be fully informed about the benefit and risks of the IPM procedure, how a particular procedure is conducted, potential rare but serious complications, and alternative options should be reviewed. The patients and guardians should be informed that IPM techniques have limitations, and responses may vary for different patients and different chronic pain conditions. The details of procedures, setting appropriate expectations, long-term benefits and risks must be explained in days or weeks before the scheduled procedure rather than on the day of the planned procedure. Depending on his/her age, the procedure should be discussed with the child, who is encouraged to express concerns and ask questions. The guardians must provide a written informed consent for the procedure and when appropriate (usually over age of 7 years) the child should provide assent, not only to protect the patient's right to autonomy but also to protect the physician from medical malpractice. The analgesic effect of a single intervention is typically temporary and may offer little to no long-term pain relief. These IPM techniques are often performed in a series to achieve longer duration of analgesia or discontinued if no benefit obtained. Younger children and anxious adolescents may require intravenous sedation or general

anaesthesia, which will require additional preparation. The absolute contraindications for IPM technique are same as in adults including presence of infections at the site of the procedure, intake of anticoagulants, a history of coagulopathy, and hyperglycaemia.

## Pharmacology of agents

The most common medications used in paediatric interventional pain management include local anaesthetics and corticosteroids.

### Local anaesthetics

Local anaesthetics are reversible voltage-gated sodium channel blockers, and blockade of (Na<sup>+</sup>) ion influx leads to inhibition of nociceptive impulse propagation. The success and safety of a nerve blockade depends on delivery of the optimal dose and volume of a local anaesthetic, preferably at the precise site of the suspected pain generator foci of a nerve or plexus. Adding 1 ml of sodium bicarbonate 8.4% to each 10 ml of a local anaesthetic (e.g. lidocaine or mepivacaine) or 0.1 ml to 10 ml of bupivacaine can hasten the onset of the nerve blockade and lessen the discomfort associated with the local anaesthetic injection. Amide local anaesthetics, such as lidocaine, bupivacaine, and ropivacaine have delayed hepatic clearance in infants less than 2 months and variable clearance between 3 and 6 months. Reduced plasma proteins (albumin and alpha-1 glycoproteins) in this age group increase the unbound and free local anaesthetic concentration that is potentially available to cause central nervous system (CNS) and cardiac toxicity. Similarly, ester local anaesthetics such as chloroprocaine are metabolized at a lower rate in infants under the age of 6 months due to decreased plasma cholinesterase activity (Mazoit and Dalens, 2004).

### Steroids

Glucocorticoids are commonly used anti-inflammatory drugs and suppress inflammatory process through many routes despite its limited efficacy. It is most frequently used via lumbar and caudal epidural routes for targeting the radicular pain of L5, S1, and other nerve roots. They exert their action by blocking the synthesis of prostaglandins, leukotrienes, and platelet activating factor. Steroids also stabilize the neuronal membrane and so are used to reduce pain from neural irritability and diminish perineural inflammation and oedema. There is no supporting scientific evidence in children, but a maximum series of three nerve blocks are proposed, to achieve longer-term relief. There is no consensus on the type or optimal dose of steroids that should be used for various central and peripheral nerve blocks in adults and no data in children. The most common steroid preparations used include triamcinolone, methylprednisolone acetate, and dexamethasone. Even though the first two are particulate steroids with better efficacy, the potential risk of vascular injury and infarction makes their use undesirable. The main risks of repeat injections of steroids are systemic absorption and Cushing's syndrome, skin atrophy, and poor healing. The use of steroid for interventional chronic pain in children is not approved by Federal Drug Administration in US (Eckel and Bartynski, 2009).

### Correct needle placement technique

Although many axial and peripheral nerve blockades have traditionally been performed without aids to correct placement a

number of options may now be utilized to improve accuracy and safety of the procedures:

- ♦ Nerve stimulation aims to stimulate the motor component of a mixed peripheral nerve to elicit painless muscle contraction. A current of usually between 0.4 and 0.5 mA is the threshold current at lowest twitch response. Higher current intensity should not be used to avoid stimulating the sensory component and causing painful paraesthesia. Responses at lower currents may indicate contact with the neural tissue and potential for inadvertent intraneural injection (Abrahams et al., 2009).
- ♦ Fluoroscopic guidance (i.e. X-ray image intensifier or a C-arm X-ray system with injection of radiopaque contrast to confirm needle tip position) for epidural steroid injections and other IPM techniques enhances accuracy of locating the target tissue and reduces the potential injury to the surrounding structures. Safe and efficient use of these modalities requires formal training, skills and experience, with attention to minimizing radiation exposure to patients' vital organs and clinicians (Eckel and Bartynski, 2009; Hodge, 2005).
- ♦ Ultrasound imaging allows visualization of soft tissue, bony, vascular, and neural structures, and can differentiate various tissue planes and spaces (e.g. epidural, intrathecal, pleural and peritoneal). The operator can confirm desirable spread of the injectate in real time. Ultrasound imaging avoids radiation and is virtually without side effects (Peng and Narouze, 2009).

## Interventional pain management for CRPS

### Sympathetic ganglion blockade

Sympathetic ganglia blockade with local anaesthetics may be used as a diagnostic test, and a positive response is interpreted as sympathetically mediated pain (SMP), however, this view is not shared by all researchers and is not supported by rigorous investigation. Although favourable responses to sympathetic blockade has been used to predict pain relief from implanted spinal cord stimulators in adult patients with CRPS, the evidence is weak (Bogduk, 2002; Sharma et al., 2006). Response to sympathetic ganglion blockade success could not be predicted from any of the presenting signs or symptoms (Sethna and Berde, 2012; van Eijs et al., 2012).

Sympathetic ganglia blockade and/or epidural analgesia must be offered in the context of multidisciplinary management of chronic pain disorders. Preliminary experience in rehabilitation of children and adolescents with intractable CRPS reported significant improvement in many domains of the child's quality of life including pain reduction, functional improvement to remission, return to normal activities, and improvement of school attendance after a 3-week outpatient intensive interdisciplinary rehabilitative programme, consisting of physical and occupational therapies, cognitive-behavioural therapy, and child and family education (Logan et al., 2012).

### Stellate ganglion blockade

The stellate ganglion is located on the anterior surface of C7 transverse process. Sympathetic innervation to the head and neck arises from T1/T2 and passes through the stellate ganglion; and the sympathetic innervation to the upper extremity arises from T2 to T8, but some fibres synapse at the second thoracic ganglion and may not be fully interrupted by a stellate ganglion blockade (Tong and

Nelson, 2000). Blockade is achieved by injection of 3 to 5 ml of local anaesthetic; larger volumes may spread to the somatic nerve via epidural sleeves, or cause serious systemic toxicity if inadvertently injected in a vessel (particularly the nearby vertebral artery). Signs of successful sympathetic blockade include: ipsilateral Horner's syndrome, nasal congestion, cutaneous vasodilation, and increased cutaneous temperature in the arm. Stellate ganglion blockade is infrequently performed in children because CRPS affects predominantly the lower extremity. Recent cases report use for post-traumatic headache, and pain management of acute herpes zoster ophthalmicus using an indwelling catheter for injection of a series stellate ganglion blockade (Agarwal and Joseph, 2006; Chan and Chalkiadis, 2010; Elias and Chakerian, 1994).

### Lumbar sympathetic blockade

This procedure is the more commonly performed in children for management of CRPS-I which predominantly affects the lower extremity (80–90%). It is typically performed at L2 to L3 level, and the technique is similar to that described in adults (Meier et al., 2009, Sethna and Wilder, 1993). Successful sympathetic blockade is indicated by interruption of sympathetic innervation to the skin manifested by vasodilation, increased blood flow and rise in skin temperature of the ipsilateral limb (Irazuzta et al., 1992; Krumova et al., 2011). Despite widespread use of sympathetic blockade in pain management clinics, only a few controlled trials have shown significant differences between sympathetic blockade and control. Systematic reviews have concluded that the overall evidence for therapeutic benefit for temporary or neuroablative sympathetic interruption for CRPS is weak (Sethna and Berde, 2012).

The precise mechanism(s) of CRPS is complex and remains a research challenge, as it involves somatosensory, motor, and sympathetic nervous systems. Potential mechanisms include: disordered regulation of sympathetic system with sympathetically maintained pain, peripheral and central sensitization, somatosensory and body perception changes (Krumova et al., 2011; Price et al., 1998). In a few CRPS patients, a series of temporary blockade with local anaesthetics leads to long-lasting pain relief (Krumova et al., 2011; Meier et al., 2009; Price et al., 1998), but the long-term benefit of sympathetic blockade in children and adults has not been investigated or demonstrated (Perez et al., 2010; Wilder et al., 1992). As an alternative technique, epidural and peripheral nerve blockade with indwelling catheters has been used for continuous infusion of local anaesthetic to alleviate CRPS pain and facilitate physical therapy for mobilization of the affected limb (Dadure et al., 2005; Sethna and Wilder, 1993).

A recent controlled trial in children with CRPS, ages 7 to 17 years, demonstrated thermal and mechanical quantitative sensory abnormalities suggestive of central sensitization (Sethna et al., 2007). A second double-blind, placebo-controlled crossover trial by the same investigators compared intravenous versus lumbar sympathetic blockade with lidocaine in a small number of children (ages 10–18 years) and found that a single lumbar sympathetic blockade produced significant reduction in pain intensity in response to evoked tactile and mechanical stimulation, mechanical temporal summation and spontaneous pain scores in approximately 40% of the patients. The findings of this study support the concept that in some patients a component of pain involves a sympathetic efferent and somatic afferent cycle of activities, and suggest that selective sympathetic ganglia blockade can alleviate pain (Meier et al., 2009).

### Complications

Potential serious infectious complications can occur with temporary epidural catheters and SCS, particularly in immune suppressed children due to malignancy, chronic steroid therapy, chronic pain disorders or those with coexisting infection (Aram et al., 2001; Olsson et al., 2008; Sethna et al., 2010; Strafford et al., 1995). In a large paediatric population the incidence of externalized (through a short subcutaneous tunnel) tunnelled epidural catheter-associated cellulitis, paravertebral muscle, and epidural space infections was evaluated and significantly higher rate of infection was found in children with CRPS when compared to postoperative children: 3.2% versus 0.06% (Sethna et al., 2010). The median duration of epidural infusion was similar in the two groups of patients (3 versus 4 days, ranging 1–12 days). The diagnosis of the infection in CRPS children (10–16 years) was made between 3 and 5 days after insertion of the catheters. All CRPS children were otherwise healthy whereas the children who developed postoperative epidural catheter-associated infection were immunosuppressed due to malignancy and/or chronic steroid therapy. The most common pathogen was *Staphylococcus aureus*. The reasons for the higher incidence of infection in otherwise healthy CRPS children are not entirely understood, but are attributed to impaired immune response caused by chronic pain and stress.

### Spinal cord stimulation (SCS) for intractable CRPS

Adult controlled trials of intractable CRPS reported that SCS significantly reduced pain (more than 50%) with SCS, but did not alleviate sensory abnormalities of allodynia or improve function (Kemler et al., 2004). Regrettably, the long-term benefit at 3-year follow-up waned and was not statistically different compared to control group. The benefit of SCS for management of challenging cases of CRPS-I in children has been reported in one retrospective review of 7 children ages 11 to 14 years who benefited transiently from sympathetic blockade with local anaesthetic (Olsson et al., 2008). The duration of SCS ranged from 3 weeks to 4 years. The pain alleviation onset occurred after 1 to 2 weeks and complete relief at 2 to 6 weeks in five patients, which persisted for 1 to 8 years; but in two patients there was only partial relief. In one patient after a few-day trial, the SCS was removed due to local infection, but the pain reduction persisted, and a recurrence some months later resolved spontaneously. Follow-up data were collected via telephone interviews and only three out of seven patients responded favourably to the question 'Would you have SCS again?'. In view of the limitations of this retrospective review and invasiveness of the procedure, prospective placebo-control trials are needed before application of this intervention can be justified (Olsson et al., 2008; van Eijs et al., 2012).

### Neuraxial blockade for intractable cancer-related pain

Many of the principles and fundamental tenets of adult palliative care are applied to refractory paediatric cancer and chronic non-malignant pain conditions, but bearing in mind the differences in child development, pharmacology, and the spectrum of malignancies.

For the majority of children (90–95%) with cancer, pain is effectively managed with conventional analgesics (opioids, non-opioids, adjuvants) via parenteral, enteral, subcutaneous, and transdermal routes (Collins, 2002). Analgesia requires optimization as parents reported only 27% of children with end-stage cancer pain

received adequate conventional analgesia (Wolfe et al., 2000). Pain complaints, other than headache, were reported more commonly in children with solid tumours including brain and nervous system, compared to other types (leukaemia, lymphoma, etc.). In last days of life 92% of children with all types of childhood malignancy reported pain and in approximately two-thirds of these patients the pain constituted a difficult problem to manage (Goldman et al., 2006).

In a small number of children even large doses of opioids do not adequately control pain, because of development of opioid tolerance and/or opioid-induced hyperalgesia; or because severe diffuse pain, involving somatic, neuropathic, and visceral components, develops. During the terminal stages of childhood malignancy, the opioid requirement may escalate exponentially to massive doses. Approximately 3% to 6% of these patients can benefit from interventional pain therapies for management of the refractory pain unresponsive to standard cancer and conventional analgesic therapies, or because opioid dose escalation is limited by intolerable side effects such as nausea, vomiting, sedation, and obtunded mentation (Collins et al., 1995, 1996).

Interventional therapies are offered when the overall benefits outweigh the risks. Such therapies include epidural, intrathecal, plexus, and peripheral nerve analgesic infusions or ablative therapies. The published experience in children is very limited but includes (Table 46.1):

- ♦ Neuraxial blockade via an epidural (caudal, lumbar, thoracic, cervical) or intrathecal catheter.
- ♦ Externalized catheter and infusion for peripheral nerve blockade.
- ♦ Neurolytic nerve and plexus blockade.

### Efficacy and safety of continuous infusion of neuraxial analgesics

Several paediatric cancer case reports and small series of have reported effective analgesia with short-term (weeks to months) use of externalized and internalized epidural and intrathecal catheters for infusion of various combinations of opioids, local anaesthetics, and clonidine (Tables 46.1 and 46.2). The spread, absorption, and pharmacodynamics of analgesics administered via epidural and intrathecal routes in children are influenced by multiple factors such as the age, weight, height, presence of increased intra-abdominal and intrathoracic pressure, cerebrospinal fluid (CSF) flow characteristics, and patency of the epidural space. There is no clear standardization or consensus for the use of various analgesics, either given alone or in combination, in children. Most approaches are derived from paediatric acute pain management studies and clinical experience. The published experience (and our own) would suggest starting with a single analgesic for patients who are on systemic opioid and other adjuvants such as a local anaesthetic for epidural administration, and opioids for intrathecal administration for the first 24 h. Combinations of analgesics are used when pain is not adequately controlled (e.g. an opioid plus local anaesthetic and/or clonidine) to enhance analgesia and/or reduce dose requirements of an individual analgesic agent and minimize the side effects. As the need for systemic opioids reduces a second agent may be added (e.g. opioid to epidural solution, or local anaesthetic to intrathecal solution). Morphine and hydromorphone are the most commonly

used opioids. The initial dose is estimated by conversion of the total daily dose of enteral and parenteral opioids. The average ratio of opioid conversion between routes, for instance, for morphine oral:intravenous:epidural:intrathecal is 3:1:0.1:0.01 mg respectively (Krames, 1996). Initially, frequent dose adjustment is required to titrate analgesic dose, concentrations and volume against individual response. Additional small doses may be necessary for breakthrough pain.

Regular monitoring for side effects is required, with close nursing observation, continuous electrocardiogram, chest wall impedance plethysmography, and pulse oximetry. In addition, systemic opioids should be gradually reduced as neuraxial analgesia is titrated up, to avoid opioid withdrawal symptoms. In terminally ill children the analgesic requirement by all routes of administration may escalate to massive doses (Queinnec et al., 1999; Whyte and Lauder, 2012).

Inadequate analgesia with neuraxial delivery has been reported in a few children with advanced and extensive malignancy, particularly with the epidural route, and which necessitated conversion to intrathecal analgesia (Collins et al., 1996; Portas et al., 1998; Queinnec et al., 1999; Tobias, 2000). Children with extensive visceral and pelvic malignancy refractory to intrathecal analgesia may require neurolytic intrathecal or coeliac blockade (Galloway et al., 2000; Patt et al., 1995; Shimazaki et al., 2003), and one rare case of cordotomy has been reported in a 10-year-old child (Queinnec et al., 1999).

### Contraindications

Many of the absolute contraindications for placement of epidural, intrathecal, and peripheral nerve blockade in healthy patients are considered to be relative contraindications in children with uncontrolled cancer pain. Advanced malignancy is associated with immune suppression and possible coagulopathy, but complications and particularly infections are surprisingly low (Anghelescu et al., 2010). Benefits should outweigh the potential side effects, and patients and their families must be fully informed of the potential serious side effects.

### Neuraxial delivery systems

A percutaneous tunnelled epidural or intrathecal catheter connected to a regular syringe pump may be used when life expectancy is limited to days or a few weeks. For children with longer life expectancy (weeks to a few months), an implanted delivery system is a better therapeutic option to reduce catheter displacement and the risk of infection. Intrathecal delivery circumvents incomplete epidural absorption kinetics, irregular spread of analgesic solution, and formation of catheter tip granulomas. Smaller volumes of analgesic are required, which is more convenient for children being cared for in the community (Galloway et al., 2000; Queinnec et al., 1999; Tobias, 2000).

Before proceeding with implantation of the drug delivery system, all patients must undergo a screening trial of intrathecal or epidural analgesia for at least 24 h to ensure pain reduction of 50% or greater and/or reduction in opioid requirement, as well as observing for potential drug reactions. It is advisable to use fluoroscopic guidance and inject contrast to ensure correct catheter placement, and epidural catheter tips should be placed at the optimal spinal dermatome to cover the location of maximum pain (Collins et al., 1996;

Queinnec et al., 1999). In addition to meticulous attention to aseptic handling of externalized and internalized catheters, catheters should be clearly labelled to avoid inadvertent administration of drugs not intended for epidural or intrathecal therapy. All drugs used for epidural and intrathecal administration should be preservative free to minimize the risk of neurotoxicity.

In adults, the subcutaneous Port-A-Cath™ device has been used for delivery of opioids via epidural and intrathecal routes for long-term management of cancer and non-malignant intractable chronic pain syndromes (Dahm et al., 1998; Plummer et al., 1991). A special Port-A-Cath system™ is designed specifically for analgesic drug delivery and repeated access to the epidural or

**Table 46.2** Clinical data on neuraxial and peripheral nerve blockade infusion reported in the literature

Site of administration and analgesic agent <sup>a</sup>	Dose
<b>Epidural opioid and clonidine (mcg/kg/h)</b>	
Lumbar morphine	1–4

<sup>a</sup>The lower rates of infusion are for initial dosing. The higher rates of infusion of opioids and/or local anaesthetics were administered to children tolerant to opioids.

intrathecal space. A subarachnoid or epidural silicon catheter is tunnelled subcutaneously to a small reservoir that has a self-sealing silicone septum for needle insertion and connection to an external infusion device. Successful use of epidural or intrathecal Port-A-Cath system™ has been reported in paediatric case reports for delivery of opioid, local anaesthetic and clonidine (Table 46.1) (Galloway et al., 2000; Queinnec et al., 1999; Tobias, 2000). In one case the Port-A-Cath system™ was used for epidural analgesia on four occasions with effective analgesia over 143 days. Complications occurred on two occasions: a catheter dysfunction, and abscess that necessitated removal of the system (Queinnec et al., 1999).

In the past decade fully implanted intrathecal pumps have been used for infusion of baclofen to manage intractable spasticity. The drawbacks of this system are potential technical problems, it requires a surgical procedure and a special percutaneous needle and kit for accessing and refilling the pump reservoir, and the high cost makes it impractical for children with cancer-related pain and limited life expectancy.

Although the use of subcutaneous implanted systems in children is appealing, in reality the full potential for delivery of various

combinations of analgesic agents is yet to be realized with respect to efficacy, failure rates, and technical complications.

### Complications of neuraxial infusions

In children, estimation of the incidence of adverse events with neuraxial infusion is not possible due to the small number of retrospective cases reported, and because many side effects either did not occur or were not documented. Systemic toxicity has occurred with large doses of epidural bupivacaine (3–4 mg/kg/h) in three patients (Portas et al., 1998). Cases of tolerance or tachyphylaxis to opioid and/or local anaesthetics were treated by converting to another analgesic with a different mechanism of action, or adding clonidine to enhance analgesia (Angelescu et al., 2010; Berde et al., 1990a; Whyte and Lauder, 2012). Drug-related side effects have included: urinary retention, which usually improved with time (Collins et al., 1996; Queinnec et al., 1999); constipation (Queinnec et al., 1999); mild reversible somnolence and respiratory depression (Berde et al., 1990a; Collins et al., 1996). Other potential side effects and complications such as nausea, vomiting, pruritus, opioid-induced myoclonus and hyperalgesia, CSF-hygrolysis, implantation pocket seroma, meningitis, and cardiovascular instability and death were not reported in these paediatric case reports. Reported catheter-related or technical complications include: catheter leakage and fracture (Angelescu et al., 2010); epidural catheter occlusion by tumour or kinking (Angelescu et al., 2010; Collins et al., 1996); catheter dislodgement (Angelescu et al., 2010; Aram et al., 2001); and Port-A-Cath system malfunction (Queinnec et al., 1999); post-dural puncture headache (Collins et al., 1996); and infection at the skin entry port or catheter tip (Aram et al., 2001; Berde et al., 1990a; Queinnec et al., 1999).

### Plexus blockade for intractable malignant and chronic non-malignant pain

The coeliac plexus is located at the T12/L1 vertebral level, anterior to the aorta and crus of the diaphragm, and supplies sympathetic innervation to the upper abdominal viscera (liver, gall bladder, spleen, stomach, pancreas, kidneys, small bowel, and proximal two-thirds of the large bowel). The preganglionic sympathetic innervation consists of T5 to T12 spinal segments. It supplies sympathetic supply to greater splanchnic nerve (T5–10), lesser splanchnic nerve (T10–11) and least splanchnic nerve (T11–12) (Loukas et al., 2010; Kambadakone et al., 2011; Puli et al., 2009). The standard coeliac plexus blockade is performed in adults with the aid of imaging or under direct vision during surgery (Arcidiacono et al., 2011; Kambadakone et al., 2011; Levy et al., 2012; Sharma et al., 2011).

Coeliac plexus blockade is primarily indicated for cancer and life limiting/terminating conditions. The principles of pain management and palliative care in adults are incorporated in the care of children with cancer, including use of neurolytic blockade. Drugs (e.g. alcohol, phenol) and dosing regimens in paediatric case reports have been based on the age of the child and extrapolation from adult experience. Neoplastic diseases such as pancreatic and hepatic malignancies can produce intense pain from stretch, compression, invasion, or distension of the visceral structures. Neurolysis of the coeliac plexus is an important adjunct for relief of intractable pain, aiming to optimizing analgesia and reduce the need for, and adverse effects of, opioid and non-opioid analgesics. As neurolytic blockade is associated with potential serious side

effects, this modality of intervention is offered when the benefits clearly outweigh the potential risks.

In children, CT-guided coeliac blockade has safely achieved effective pain management in a small number of patients aged 3 to 7 years. Reported cases include:

- ♦ Neurolytic block for management of refractory upper abdomen visceral pain from cancer (Berde et al., 1990b; Staats and Kost-Byerly, 1995).
- ♦ Neurolytic splanchnic nerve blockade in an 18-year-old with mitochondrial neurogastrointestinal encephalopathy and superior mesenteric artery syndrome for management of intractable abdominal pain, which resulted in pain relief at one-year follow-up (Celebi et al., 2006).
- ♦ Diagnostic and temporary treatment of acute on chronic pancreatitis with local anaesthetic and steroid (Attila et al., 2009; Goldschneider et al., 2007).
- ♦ Chronic abdominal pain due to inflammatory bowel disorder (Tanelian and Cousins, 1989) or due to neurodegenerative disorders (Goldschneider et al., 2007; Teitelbaum et al., 2002).

*Superior hypogastric plexus blockade* (anterior to lower third of L5 and upper two-thirds of S1 vertebral bodies) has been used in adults for management of intractable pain of the pelvic organs and descending colon and rectum as well as perineal hyperhidrosis (Schmidt et al., 2005; Nabil and Eissa, 2010).

*Ganglion impar*, a small ganglion formed by convergence of the two pelvic sympathetic trunks in front of the sacro-coccygeal junction, supplying perineum, distal rectum, anus, distal urethra, vulva and distal third of the vagina. A trans-sacrococcygeal block with local anaesthetic successfully managed chronic post-traumatic coccydynia in an adolescent (Ellinas and Sethna, 2009). Neurolytic blockade, with appropriate imaging and confirmation of a successful diagnostic local anaesthetic block, has been used for adult malignant pain conditions unresponsive to conventional treatment (Lin et al., 2010).

## Interventional pain management for intractable acute and chronic pain

### Neuraxial blockade

Safe and effective (defined as decrease in mean dose of opioid requirement) use of short-term caudal, lumbar and thoracic epidural infusions via tunnelled catheters are also reported in a small number of 14 children and adolescents, a mean age 4.4 years, and a mean duration of 16 days (range 5–14 days) for management of pain following trauma, extensive surgery and CRPS type I (Aram et al., 2001). Long-term continuous peripheral nerve block has also been used for management of severe pain from pathological fracture of the femur in 3 children, aged 8, 13, and 14 years, with osteosarcoma while awaiting chemotherapy and surgical treatment. The duration of the externalized catheters was 22 to 41 days with significant reduction in pain and opioid use, and without complications related to the catheter, infection or local anaesthetic toxicity (Burgoyne et al., 2012b).

### Phantom limb pain (PLP)

In children, the clinical characteristics, preventive measures and treatment of PLP have not been investigated rigorously, with only

a few retrospective reviews and one prospective study in small numbers of paediatric patients (Krane and Heller, 1995; McGrath and Hillier, 1992; Melzack et al., 1997; Simmel, 1962; Smith and Thompson, 1995; Thomas et al., 2003; Wilkins et al., 1998). The current pharmacotherapy is inadequate to completely prevent or alleviate the pain after limb amputation in children and adults. The development of PLP is best conceptualized as multifactorial and treatment requires a multimodal approach. See elsewhere in this volume for further description of PLP (Walker, Chapter 21), and for pharmacological management options (Rastogi and Campbell, Chapter 48). While PLP cannot be entirely prevented after surgery, growing anecdotal data suggests that perioperative neuraxial and peripheral nerve blocks in addition to systemic analgesics may minimize the immediate and short-term post-amputation PLP. A recent review of cancer amputee children and young adults reported a very lower incidence of only 10% of PLP at 1 year after amputation (Burgoyne et al., 2012a). In this review 17 out of 25 patients had pain prior to amputation and the low incidence post-surgical PLP was partly ascribed to the preoperative pain management. This included administration of gabapentin in all patients and continuous epidural or continuous peripheral nerve blockade in 21 out of 26 cases.

### Epidural steroid injection (ESI)

The indication for ESI is local alleviation of perineural inflammation of the spinal nerve roots that are irritated or compressed by herniated nucleus pulposus, annular tear, spinal stenosis and post-laminectomy syndrome. Fluoroscopic-guidance is used to place steroid in the vicinity of the affected nerve roots. Evidence for ESI is restricted to adult practice, predominantly for radicular pain that radiates along the distribution of a specific spinal nerve distally below the knee. Radicular pain is neuropathic pain in the distribution of specific spinal nerve roots, and can arise from mechanical or chemical irritation due to a herniated nucleus pulposus or spondylosis with stenosis of nerve pathways (Manchikanti et al., 2012).

*Interlaminar epidural steroid injections* may be performed in the cervical and lumbar spine using the traditional loss of resistance technique. For accurate placement of the needle, within the epidural space and close to the affected nerve fluoroscopic guidance is recommended to avoid misplacement of the needle and confirm spread of contrast medium in proximity to the target spinal nerve. In adults, typical injectate is 80 mg (2ml) of triamcinolone. In the lumbar region a small amount of local anaesthetic is added to produce pain relief. In the cervical spine local anaesthetics are avoided to minimize excessive cephalad spread of the injectate (Manchikanti et al., 2012).

*Transforaminal epidural steroid injections* is intended to deposit the medication around the nerve root sleeve for more accurate targeting of the affected nerve in the anterior epidural space where disc herniation occurs. It is primarily performed in the lumbar spine under fluoroscopic guidance. In adults, typical dose is 40 mg (1ml) of triamcinolone, with or without a small amount of local anaesthetic (Manchikanti et al., 2012; Quraishi, 2012).

*Selective spinal nerve blockade* (SNRB) is a diagnostic technique to determine if a specific nerve root is the source of pain prior to surgical removal of the offending ruptured intervertebral disc. The needle tip is placed just outside of the neural foramen, lateral to the position for transforaminal ESI site but outside the foramina.

*Caudal epidural steroid injection* is performed by a technique similar to that performed for caudal anaesthesia, with lateral fluoroscopy to visualize the spread of contrast medium (Parr et al., 2012).

### Facet joint pain

The facet joint is formed by articulation of processes of two adjacent vertebrae and the joint capsule is innervated by a medial nerve branch. The joint is susceptible to chondral damage (e.g. whiplash injury, repetitive strain, sports injury), inflammation and degeneration (e.g. congenital, post-surgical spinal fusion, old age). Estimation of the true incidence of facet joint pain is difficult because the diagnosis cannot be made by history, physical examination or imaging, and the most reliable diagnostic test is response to intra-articular or medial nerve branch blockade (Schwarzer et al., 1994a, 1994b). Although some studies report pain relief up to one year, the lack of RCT crossover studies precludes drawing definitive conclusions about specificity of this blockade.

*Intra-articular facet blockade* is performed with local anaesthetic and steroid, and repeat injections may be required to relief flare-ups. If the pain recurs some practitioners consider positive response to steroid injection a criterion to perform radiofrequency lesioning for providing prolonged pain relief (Atluri et al., 2008; Boswell et al., 2007).

*Medial branch nerve blockade (MBB)* interrupt pain conduction by nerves that innervate the facet joints. MBB is performed using a local anaesthetic alone or in combination with steroids, potentially followed by a series of blocks, or radiofrequency lesioning to provide prolonged pain relief.

*Radiofrequency nerve lesioning (RFNL)* (thermo-coagulation or thermal injury) is utilized to interrupt nerve conduction for 6 to 9 months. Although RFNL is used for interruption of various nerves, e.g. peripheral (e.g. occipital neuralgia), visceral (e.g. splanchnic) and sympathetic (e.g. CRPS), presently it is primarily used for the treatment of axial back pain produced by facet and sacroiliac joint arthropathy, and therefore is most often used in adults (van Boxem et al., 2008). Pulsed RFNL was introduced recently because of a wider margin of safety, and to expand the application of this therapy to various peripheral neuropathies, joints arthropathy and painful trigger points as well as treatment of facet joints, sacroiliac joints, dorsal root ganglion, stellate ganglion, Gasserian ganglion and intervertebral discs (van Boxem et al., 2008).

### Sacroiliac joint injection

The sacroiliac joint connects the pelvis to spine, has limited mobility and is a major source of low back pain in aged adults secondary to degenerative processes of the intra-articular cartilage. In adolescents, sacroiliac joint pain may follow trauma, particularly sports injury. There is no one clinical test that reliably confirms that the pain emanates specifically from the sacroiliac joint and diagnosis is based on a combination of clinical tests of the sacroiliac joint and radiographic imaging. Most patients benefit from anti-inflammatory drugs and physical therapy. Some support performance of diagnostic/therapeutic blockade with a local anaesthetic alone or in combination with steroid. If repeated treatment is required radiofrequency nerve lesioning has been utilized in adults (Hansen et al., 2012; Simopoulos et al., 2012).

### Peripheral nerve blockade

Many different types of peripheral nerve blockade have been utilized for either diagnosis or management of various chronic pain syndromes. Local anaesthetic blockade can provide several hours of pain relief, and may aid in diagnosis or predict responses to sustained pain relief following prolonged nerve blockade techniques. Steroid provides lasting relief in cases of perineural inflammation from entrapment syndromes. Common peripheral nerve blockade used in management of adult chronic pain are described below, but for the majority evidence is limited. For many, paediatric use is predominantly for acute or perioperative pain, and the role for chronic pain management is unclear.

#### Trigeminal nerve blockade

The sensory afferent inputs from the orofacial structures that sense mechanical, thermal and pain stimuli are served by the fifth (trigeminal) cranial nerve, and divided into:

- ♦ Ophthalmic branch innervates nasal and frontal sinuses mucosa.
- ♦ Maxillary branch innervates the nares, upper teeth and gums, nasal mucosa, palate and roof of the pharynx, maxillary, ethmoid, and sphenoid sinuses.
- ♦ Mandibular branch innervates the lower teeth and gums. The trigeminal system is the main source of sensory innervations to the supra-tentorial dura, venous sinuses and meningeal arteries.

The sensory afferent input projects to the trigeminal (Gasserian) ganglion. The trigeminal brainstem sensory neuron complex receives descending inhibitory modulation from higher centres (periaqueductal grey, reticular formation and sensory-motor cortex) mediated through release of neuropeptides including endogenous opioids, noradrenaline, 5-HT, and GABA through synaptic connections (Sessle, 2000).

The classic presentation of trigeminal neuralgia (TN) is paroxysms of lancinating pain, which occur in the territory of one or more trigeminal nerve branches, associated with muscle spasms in the absence of sensory and motor deficit. The pain is easily triggered by non-noxious stimuli such as minor mechanical stimulation or light touch. Trigeminal neuralgia is rare in the paediatric age group, with case reports of typical (at ages 1.5, 6, 9, and 12 years) and atypical (at 9 years) TN described. The youngest child in whom TN was retrospectively suspected was 13 months of age; the child suffered pain attacks for years before TN was finally diagnosed at age 7 years (Bender et al., 2011).

As in adults, children in whom the medical treatment of TN is ineffective or the side effects prove unacceptable, microvascular decompression of the trigeminal nerves in the posterior cranial fossa may be indicated (Kalkanis et al., 2003; Resnick et al., 1998). There is no satisfactory long-term medical or ablative treatment for TN. In 18 children, percutaneous retro-Gasserian glycerol injection resulted in complete pain relief in 72%, good in 11%, poor 11%, and recurrence in 22%. None of the children experienced a permanent facial sensory deficit. Although this procedure is less invasive than a microvascular decompression craniotomy, its performance requires the full cooperation of an awake and non-sedated child and the long-term benefit is not known (Yue, 2004).

### Greater occipital nerve

Occipital nerve irritation or inflammation can produce localized pain or ipsilateral tension-type headache or intractable neuropathic headache. Perineural injection of a combination of local anaesthetic and steroid can relieve pain. Best results are reported for occipital nerve neuralgia presenting with shooting, stinging or burning pain and the symptoms are reproducible by pressure palpation of the occipital nerve at its exit from the skull. Some degree of temporary success is also reported for patients with unilateral migraines, cluster headaches and cervical facet arthropathy. Blockade is usually performed using surface landmarks in children and adolescents (Suresh and Voronov, 2012). Care is needed to avoid direct needle trauma of the nerve or puncturing the occipital artery, which runs lateral and parallel to the nerve. To improve safety occipital nerve block can be performed with use of ultrasound guide as described for adults (Shim et al., 2011).

### Suprascapular nerve blockade

The suprascapular nerve arises from C5 and C6 and innervates the supraspinatus and infraspinatus muscles and gives off twigs to shoulder joint. In a randomized control trial of adults with chronic shoulder pain this blockade has improved pain, range of motion and disability (Shanahan et al., 2003). This nerve blockade has been performed in adults with aid of anatomical landmarks, electromyography, computed tomography scan, ultrasound guide, or with fluoroscopy (Fernandes et al., 2012).

### Intercostal nerve blockade

Intercostal nerve blockade is performed for management of intercostal neuralgia following nerve injury or inflammation. It is also performed for diagnosis of painful conditions such as post-thoracotomy pain syndrome, and slipping rib syndrome. This procedure is commonly performed in children with the use of anatomical landmarks but ultrasound imaging may improve safety (Bhalla et al., 2012) as pneumothorax can occur if the needle is advanced deep beyond the internal intercostal muscles.

### Rectus abdominis sheath blockade

The rectus sheath consists of anterior and posterior layers that envelop the rectus abdominis muscle, which is innervated by T7 to T12. The intercostal nerves enter the rectus sheath through the posterior rectus sheath, and pierce the rectus muscles and the anterior sheath to innervate the anterior abdominal wall. In one-third of the population the intercostal nerve bypasses the rectus sheath compartment and innervates the overlying skin directly (Skinner and Lauder, 2007) and subcutaneous infiltration should be used to supplement the posterior rectus sheath blockade.

Entrapment of the nerves may occur after trauma, repetitive and excessive abdominal crunches in athletes, rectus sheath hematoma, postsurgical entrapment in a scar or suture ligation. This presents with intermittent pain at the edge of the rectus muscle sheath (entry site of the intercostal nerves), which is aggravated with contraction of the rectus muscles and alleviated by lying down and flexion of the ipsilateral hip. Differential diagnoses include hernia, irritation of intercostal nerve roots, rib-tip syndrome, myofascial pain and trigger points of the rectus muscles.

Block with local anaesthetic with or without steroid can be performed with loss of resistance technique and feel of posterior rectus sheath as an end point, ultrasound imaging clearly defines the end-point and reduces the risk of perforating the posterior rectus sheath

and bowel injury (Bhalla et al., 2012; Gurnaney et al., 2011; Skinner and Lauder, 2007).

### Ilioinguinal and iliohypogastric nerve blockade

The ilioinguinal and iliohypogastric nerves are branches of the first L1 root, occasionally with contribution from T12. The ilioinguinal nerve exits from the abdomen through the obliquus internus and accompanies the spermatic cord through superficial inguinal ring. The iliohypogastric anterior branch perforates the external oblique muscle just medial to the anterior superior iliac spine and provides cutaneous sensory innervation to the abdominal skin above the pubis. Ilioinguinal neuralgia can cause lower abdominal and pelvic pain in adults (often following direct blunt trauma, inguinal herniorrhaphy or pelvic surgery), and has been reported in adolescent athletes. The nerve is compressed as it exits the transverse abdominis muscle just lateral to anterior superior iliac spine, presenting as burning pain, paraesthesia, and infrequent numbness over the nerve's lower abdominal distribution, with radiation to the scrotum or labia and sometimes the inner upper thigh. Slouching forward may improve, and extension of the spine worsens the pain.

In children both these nerves are in close proximity between transversus abdominis and internal oblique muscle and are amenable to blockade with a single injection medial and cephalad to anterior superior iliac spine. Possible complications are perforation of the bowel if the needle further posteriorly and femoral nerve blockade if the local anaesthetic tracks down caudad. This blockade can be easily and safely performed with ultrasound guidance (Ecoffey et al., 2010; Jansen et al., 2008; Peng and Tumber, 2008; Stark et al., 1999).

### Lateral femoral cutaneous neuropathy (LFCN)

LFCN neuropathy, also known as meralgia paraesthetica, presents with paraesthesia (tingling, pins and needles), burning, cutaneous hypersensitivity to warm shower, groin pain or numbness over the distribution of the nerve on the anterolateral area of the thigh. The symptoms are aggravated by prolonged walking, standing or biking. Compression of the nerve may be due to tight clothing or belt, obesity or fast weight gain, pregnancy, pelvic pathology, local injury from direct trauma or after inguinal hernia repair. Conservative therapy includes elimination of the offending compression cause. Neuropathic pain pharmacotherapy is effective in most patients with mild pain (see Rastogi and Campbell, Chapter 48, this volume). In some patients nerve blockade at the inguinal ligament with a combination of a local anaesthetic and corticosteroid may provide pain relief for days to weeks (Fernandez-Mayoralas et al., 2010).

### Pudendal nerve blockade

The pudendal nerve arises from S2 to S4 nerve roots, passes out the pelvis through lesser sciatic foramen and crosses the ischial spine to innervate the rectum, perineum and the penis or clitoris and posterior aspect of the penis or labia majora. Injury to these nerves occurs following trauma, injury during surgery, inflammation, compression/entrapment, or due to invasion by malignancy. Pain is aggravated by sitting and alleviated by standing, sitting on toilet seat or lying on the painful side. Pudendal nerve blockade has been described in children using percutaneous transperineal approach and nerve stimulator for management of postoperative pain management (Kfoury et al., 2008; Naja et al., 2011).

## Conclusion

In adults and now in paediatric patients there have been concerns about efficacy and acceptability of the various interventional techniques for management of chronic pain disorders due to the lack of well-designed randomized control trials. Interventional techniques for management of chronic pain in children and adolescents are still being developed and there are no controlled trials on their long-term effectiveness. The best available evidence synthesized here is primarily extrapolation from adult interventional procedures for chronic pain management literature, paediatric case reports and case series, and the authors' experience. The authors of this chapter are of the view that the practitioners of paediatric interventional techniques must have a basic understanding of paediatric development, pharmacology, resuscitation skills, and competency in performing paediatric regional anaesthesia techniques as well as experience with specific adult interventional techniques for chronic pain management before applying these techniques in young patients. The readers are also advised to review the adult controlled trials and evidence-based data before integrating these techniques into paediatric practice. However, as part of multidisciplinary management of paediatric cancer and chronic pain, well-selected IPM techniques can play an important role when pain is unrelieved by conventional treatment modalities.

## CHAPTER 47

# Topical anaesthetics and analgesics

William T. Zempsky

### Summary

Topical administration of anaesthetics and analgesics can allow for the efficient, painless delivery of medications which may reduce systemic side effects associated with the medication while providing clinical advantages over injected or oral administration for the same clinical situation. Topical anaesthetics have become widely used prior to a variety of painful procedures in children including venous access, laceration repair, and injections. Topical administration of non-steroidal anti-inflammatory drugs, lidocaine, capsaicin, and other agents also are useful for a range of conditions including acute and chronic musculoskeletal pain, and neuropathic pain.

### Background

It is important to differentiate between topical and transdermal medications. Topical medications target the site of application and ideally produce effective drug concentrations locally with minimal systemic absorption. Topical anaesthetics and analgesics target the peripheral nerves and soft tissue at that site (Galer, 2001). In contrast, transdermal medications do not have to be applied over an involved site and attempt to reach systemic drug concentrations to achieve therapeutic results (Argoff, 2004). This chapter will focus on topical medications (Table 47.1).

Benefits of topical drug delivery in general may include the potential for local therapeutic drug levels with reduced side effects, painless drug delivery, improved patient adherence (which is especially important in children) and acceptance, ease of dose termination, avoidance of first-pass metabolism, and direct access to the target site.

The skin is an effective barrier to drug delivery, its primary role being to prevent the ingress or egress of compounds across it (Tadicherla, 2006). The stratum corneum, the uppermost layer of the skin consists of a thin layer of cornified non-viable keratinocytes interconnected by highly ordered lipid bilayers, and has evolved to be a highly effective barrier to water-soluble substances, which typically include anaesthetics (Houck and Sethna, 2005). Topical medications must transverse the stratum corneum to reach their site of action which may be the peripheral transducing terminals of cutaneous sensory fibres located in the dermis and epidermis (Lumpkin and Caterina, 2007), or the local soft tissues including synovial fluid, synovial tissue and cartilaginous structures (Bandalier extra, 2005) (Figure 47.1).

Three delivery methods have been utilized to bypass the stratum corneum barrier (Zempsky, 2008):

- ♦ Injection of local anaesthetics or other medications, usually via a small-gauge hypodermic syringe, is the oldest of the methodologies.
- ♦ Passive diffusion from creams, gels, or patches comprises the second general class of methodologies. Passive diffusion of topical agents require that they have a molecular weight under 500 Daltons, with a hydrophobic component to allow it to transverse the stratum corneum but also some hydrophilic features to penetrate the epidermis (Stamos, 2007).
- ♦ Active drug delivery methods which enhance the rate of drug passage through the skin and shorten the time to onset of action. There are a diverse group of technologies which facilitate the drug delivery process. These include heat-enhanced diffusion, iontophoresis, sonophoresis, laser-assisted transdermal passage, or pressurized gas delivery of powdered drug particles (Zempsky, 2008). Microporation, a newer technology, uses tiny microneedles to penetrate the stratum corneum and directly place the drug within the epidermis (Yadav, 2011).

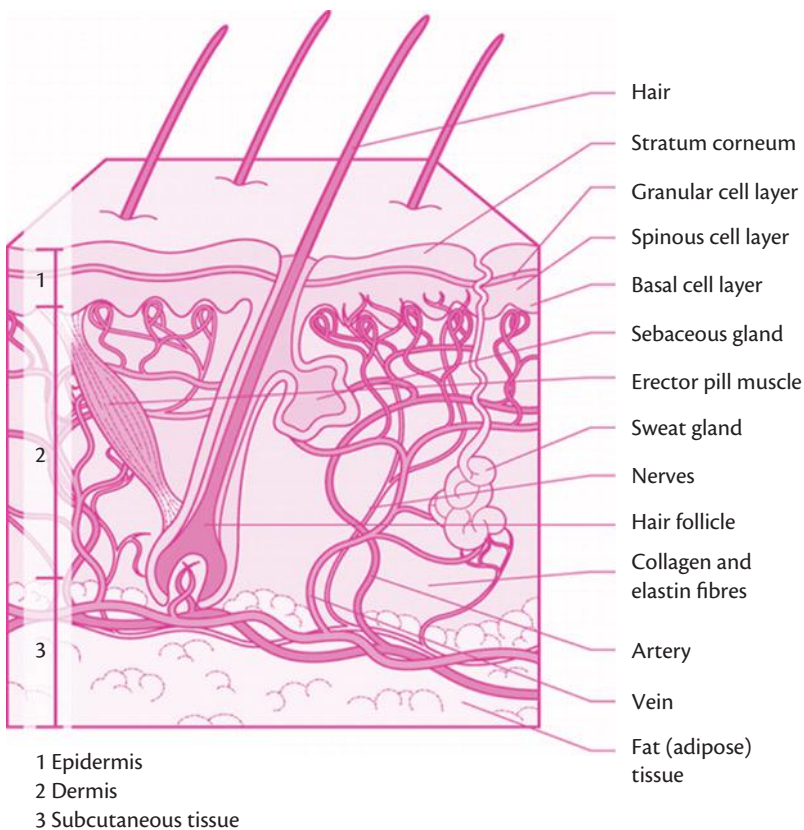

Topical as well as transdermal drug delivery is a rapidly expanding field. Most of the drugs and technologies used for topical anaesthesia have been well studied in children; however, this is not the case for topical medications used for musculoskeletal and neuropathic pain which will be discussed in this chapter. The extrapolation of use of these agents in children seem reasonable given several factors: the pharmacodynamic response to most medications including local anaesthetics, opioids, and non-steroidal anti-inflammatories (NSAIDs) are substantially mature by age 2 years, the degree of systemic absorption of these topical medications is low, and the local skin effects are for the most part minimal and short lived (Berde, 2012).

### Topical anaesthetics for procedural pain

The ideal topical anaesthetic should have good efficacy, an excellent safety profile, convenient application, enduring effect, and reasonable cost. Specific properties important for topical anaesthesia prior to a procedure include rapid onset of analgesia to minimize disruption and delay of needed medical procedures, minimal systemic

**Table 47.1** Common topical anaesthetics and analgesics

Drug	Brand or other names	Use
Lidocaine/prilocaine cream	EMLA® and others	Procedural pain
Tetracaine	Amethocaine®, Ametop®	Procedural pain
Liposomal lidocaine	LMX4®, Maxilene®	Procedural pain
Vapocoolant spray	Painease® and others	Procedural pain
5% lidocaine patch	Lidoderm®	Neuropathic and musculoskeletal pain
Topical NSAIDs	Flector®, Voltaren®, Pennsaid®, and others	Musculoskeletal pain
Capsaicin	Zostrix®, Qutenza®, and others	Neuropathic pain
Menthol and methylsalicylates	Many	Musculoskeletal pain
Ketamine and amitriptyline	Compounding pharmacist	Neuropathic pain

**Figure 47.1** Reproduced from Mark Gardiner et al, *Training in Paediatrics: The Essential Curriculum*, Figure 9.1, p.194, Oxford University Press, Oxford, UK, Copyright © 2009, by permission of Oxford University Press.

absorption, no untoward dermal effects, and no adverse effect on the success rate of the procedure (Zempsky, 2008). No commercially available agent is likely to have all of these properties.

Topical anaesthetics for procedural pain differ from one another primarily in their drug delivery mechanisms, rather than in their underlying pharmacological modes of action. Most available agents utilize lidocaine, prilocaine, and/or tetracaine (also known as amethocaine) and produce their analgesia through similar mechanisms involving inhibition of sodium ion channels in sensory neurons.

*Lidocaine and prilocaine cream*, 2.5%/2.5% (EMLA® Cream (eutectic mixture of local anaesthetics), AstraZeneca LP, Wilmington, DE) is the most well studied topical anaesthetic and has been used in clinical practice for approximately 25 years. When mixed in a

1:1 ratio, crystals of lidocaine and prilocaine produce a 'eutectic mixture', a mixture that has a lower melting point than either component alone. Within the cream, the local anaesthetics exist as a liquid oil rather than as crystals; this leads to higher concentration of anaesthetic within the oil thus an increase in the rate of diffusion into the epidermal and dermal layers. In some countries a eutectic mixture of lidocaine and prilocaine is also available in a patch formulation.

A large number of clinical trials in both children and adults have analysed its efficacy for venepuncture pain and intravenous cannulation pain (Ehrenstrom-Reiz, 1983; Hallen and Uppfeldt, 1982; D. L. Halperin et al., 1989; Lander et al., 1996; Maunuksela and Korpela, 1986; Moller, 1985). A meta-analysis of these trials concluded that lidocaine and prilocaine cream provided significant

analgesia for both venepuncture and cannulation procedures, with similar and consistent effects across both procedures, with 85% of patients receiving exhibiting significant analgesic benefit from its application prior to the procedure (Fetzer, 2002). The analgesia appears to be independent of age, location of the procedure, and intravenous insertion technique (Fetzer, 2002). Lidocaine and prilocaine cream also reduces pain associated with vaccination and has not been shown to impact immunogenicity (S. A. Halperin, 2000).

The efficacy of lidocaine and prilocaine cream is dependent upon dosage and application time. A thick layer (2.0 ml) is more effective than a thin layer (0.5 ml) in reducing pain (Sims, 1991). The minimum recommended treatment time is 60 min, but longer durations (>90 min) are known to produce greater pain relief (Houck and Sethna, 2005). Protocols (such as application in triage in the emergency department) can overcome the practical challenge of delayed onset of anaesthesia for use in clinical settings.

Lidocaine and prilocaine cream is efficacious and safe for use in neonates and prematures down to 26 weeks for blood drawing (Taddio, 1998), lumbar puncture (Kaur, 2003), suprapubic aspiration (Nahum, 2007) and circumcision (Taddio, 1997, 1998). Efficacy for heel lancing has not been demonstrated (Taddio, 1998). For neonates 0 to 3 months of age or in any child less than 5 kg, maximum total dose of lidocaine and prilocaine cream should be 1 g, the maximum application area should be 10 cm<sup>2</sup>, and the maximum application time should be 1 h (Taddio et al., 1998) (Table 47.2).

Lidocaine and prilocaine cream causes vasoconstriction, which leads to blanching of the skin. Allergic and anaphylactoid reactions associated with lidocaine or prilocaine can rarely occur. In young infants who do not have adult levels of methaemoglobin reductase, in patients who are on medications which put them at increased risk, or have prolonged application times use of lidocaine and prilocaine cream may be associated with methaemoglobinaemia. However methaemoglobinaemia was not demonstrated with appropriate use of this agent in neonates (Taddio, 1998).

*Tetracaine or amethocaine gel* (Ametop Gel™, Smith & Nephew, London, UK), currently available in Australia, Canada, New Zealand, and the UK, consists of 4% tetracaine base in an aqueous gel (Obrien et al., 2005). When applied to skin, solid tetracaine particles liquefy to form an oil emulsion that better penetrates the stratum corneum (Obrien et al., 2005). Like lidocaine and prilocaine cream, tetracaine gel is usually applied with an occlusive dressing.

Tetracaine gel has been demonstrated to provide comparable anaesthesia to lidocaine and prilocaine for venous access and other dermal procedures (Bishai et al., 1999; Lawson et al., 1995; Rømsing et al., 1999). For intravenous cannulation a tetracaine gel is preferred over lidocaine- prilocaine cream (Lander, 2006). In neonates, tetracaine is effective for pain of venepuncture and injection but not heel lance (Jain and Ruttner, 2000; Jain et al., 2001; Shah et al., 2008). Tetracaine gel produces analgesia in 30 to 45 min, and has a longer duration of anaesthesia (4–6 h) than lidocaine and prilocaine cream (2 h) (Houck and Sethna, 2005; Lander, 2006). Tetracaine gels' prolonged duration of action may be due to a depot effect in the stratum corneum and an affinity of tetracaine for proteins, which may prolong its binding to sodium channels on sensory neurons (Obrien, 2005).

No significant systemic adverse events with tetracaine gel have been reported. Transient erythema followed by oedema and pruritus are the most common side effects (Obrien et al., 2005). Tetracaine causes vasodilation which has been theorized to facilitate vascular access (Houck and Sethna, 2005); however, in a comparative study first attempt success rates between 4% tetracaine and lidocaine-prilocaine cream were not different (75.8% versus 73.9%) (Newbury and Herd, 2009).

Liposomes are vesicles consisting of concentric lipid bilayers (phospholipids and cholesterol) that enclose an aqueous compartment (Kshirsagar, 2005). By encapsulating a drug in liposomes the surrounding bilayer protects it from *in vivo* degradation enzymes and allows fusion with other bilayers (Kshirsagar, 2005). Liposomal lidocaine 4% is available in the US (LMX4®, Ferndale Laboratories, Detroit, MI) and Canada (Maxilene®, Ferndale Laboratories, Detroit, MI) and can be used with or without an occlusive dressing.

Liposomal lidocaine 4% is efficacious in children undergoing venous access procedures (Eichenfield et al., 2002; Koh et al., 2004; Taddio et al., 2005). Procedural success rate was higher in a liposomal lidocaine 4% group compared to the placebo group in patients undergoing venous access (Taddio et al., 2005). A systematic review found liposomal lidocaine to be as efficacious as lidocaine prilocaine cream and tetracaine gel (Eidelman et al., 2005).

Safety of liposomal lidocaine is similar to other creams and gels. Adverse events are usually limited to pallor, redness, and mild itching at the application site (Eichenfield et al., 2005). Liposomal lidocaine 4% has not been investigated in great detail in children younger than 2 years of age (Zempsky, 2008).

**Table 47.2** Lidocaine and prilocaine cream maximum recommended dose, application area, and application time by age and weight (EMLA® package insert, n.d.)

Age and body weight	Maximum total dose	Maximum application area	Maximum application time
0–3 months or <5 kg	1 g	10 cm <sup>2</sup>	1 h
3–12 months and >5 kg	2 g	20 cm <sup>2</sup>	4 h
1–6 years and >10 kg	10 g	100 cm <sup>2</sup>	4 h
7–12 years and >20 kg	20 g	200 cm <sup>2</sup>	4 h

Please note: if a patient greater than 3 months old does not meet the minimum weight requirement, the maximum total dose of lidocaine and prilocaine cream should be restricted to that which corresponds to the patient's weight.

These are broad guidelines for avoiding systemic toxicity in applying lidocaine and prilocaine cream to patients with normal intact skin and with normal renal and hepatic function. For more individualized calculation of how much lidocaine and prilocaine may be absorbed, physicians can use the following estimates of lidocaine and prilocaine absorption for children and adults: the estimated mean (±SD) absorption of lidocaine is 0.045 (±0.016) mg/cm<sup>2</sup>/h; the estimated mean (±SD) absorption of prilocaine is 0.077 (±0.036) mg/cm<sup>2</sup>/h.

Unlike the other topical anaesthetic options, vapocoolant sprays do not rely on a chemical anaesthetic. Instead, they rapidly cool the skin, which slows initiation and conduction of impulses in cutaneous sensory nerves and increases their refractoriness (Burke et al., 1999). Composed of volatile liquid refrigerants, vapocoolant sprays are applied to the skin and their rapid evaporation produces a short-lived (<1 min) anaesthetic effect. These agents can be directly sprayed onto the skin or applied via saturated cotton balls.

Studies of vapocoolant sprays for prevention of procedural pain have reported mixed results. In a review of trials for venous access pain four out of eight trials could not demonstrate increased efficacy over placebo or no treatment while the other four demonstrated significant benefit (Bandolier extra, n.d.).

Studies are also inconsistent for injection pain. A vapocoolant spray provided significantly more analgesia than cold saline spray in adults (Mawhorter et al., 2004) and, when combined with distraction, provided significantly more pain relief than distraction alone in children and the analgesic effect was similar to lidocaine and prilocaine cream plus distraction (Reis and Holubkuv, 1997.) However, a meta-analysis of five studies evaluating vapocoolants for immunization did not demonstrate benefit (Shah, 2009).

The heterogeneous results provided by vapocoolants may be due to the short-lived nature of the anaesthesia, small sample sizes of the study, differences in the length of anaesthesia needed for the procedure, and varied administration technique of the vapocoolant itself (Bandolier extra, n.d.). Studies that demonstrated benefit for immunization pain applied the vapocoolant using a cotton ball held in place for 10 to 15 sec (Shah, 2009).

Use of vapocoolant sprays has been associated with some rare cases of allergic contact dermatitis, and prolonged spraying can cause hypo-pigmentation and atrophic scarring, especially in patients with poor circulation. Most vapocoolant sprays contain chemicals that are eye irritants (Bircher, 1994).

Penetration of local anaesthetics through the stratum corneum is accelerated by heat (Hull, 2002). The lidocaine/tetracaine topical patch (Synera™, Nuvo Research Inc. Mississauga, Ontario; Rapydan™, EUSA, England), has a heating component that generates a mild warming when exposed to air, and an adhesive to fix the patch to the skin (Sethna et al., 2005). The lidocaine/tetracaine patch provided superior analgesia to placebo in a paediatric venous access study of children aged 3 to 17 who received treatment for 20 min prior to venous access (Sethna et al., 2005). In an adult study the lidocaine/tetracaine patch provided superior analgesia for 10-, 20-, and 30-minute application times prior to venous access than lidocaine/prilocaine cream but at 60 min the two anaesthetics were equivalent (Sawyer 2004). The lidocaine/tetracaine patch was also equivalent to 4% tetracaine in a study of 100 adults requiring venous cannulation for day surgery. The warmth has the potential to ease venous access by dilating veins but this has not been evaluated. Adverse events with the lidocaine/tetracaine patch are limited to local irritation and erythema.

There are several other active drug delivery technologies which have been demonstrated to be effective for speeding lidocaine delivery allowing for more rapid skin anaesthesia prior to dermal procedures. The following technologies described are not currently in clinical use.

Lidocaine iontophoresis is the process where positively charged lidocaine is accelerated into the skin under the influence of a low-voltage direct electrical current (Figure 47.2). The quantity and

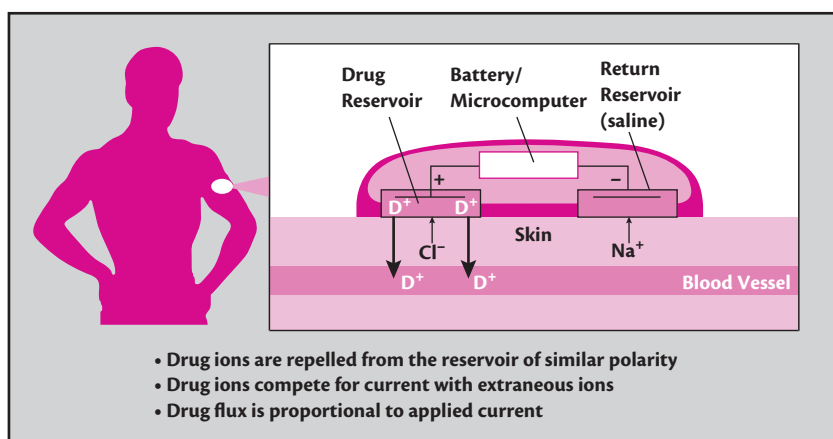

distribution of delivered drug is dependent on the ion charge, molecular weight, intensity of the electric current, concentration of the drug, contact surface area of the delivery electrode, and duration of current (Zempsky and Ashburn, 1998). Lidocaine iontophoresis provides better anaesthesia with a 10 min application than iontophoresis of placebo, and at least equivalent anaesthesia to a 60 min application of lidocaine and prilocaine cream, and lidocaine infiltration (Galinkin et al., 2002; Miller 2001; Zempsky et al., 1998, 2004). However, tingling, itching, burning sensation, and discomfort have been documented in trials, and burns, which have been reported to occur at incidences of 1 per 15 000 to 20 000 treatments, remain a concern clinical acceptability of this technology for topical anaesthesia (Rattenbury and Worthy, 1996; Zempsky et al., 1998).

The EpiTure Easytouch™ System (Norwood Abbey Ltd, Frankston, Australia), is a single-pulse laser device that can be used before dermal procedures to ablate a patch of stratum corneum 6 mm in diameter which allows for a topical anaesthetic such as liposomal lidocaine to provide anaesthesia in about 5 min (Shapiro, 2002). This system has been shown to be effective in reducing pain associated with needle procedures in healthy adults (Baron, 2003; Shapiro 2002). Mild pain, itching, and erythema of the skin may be apparent at the ablation site following treatment. Patients treated with dermatological lasers are known to experience temporary hyperpigmentation or hypopigmentation at the treatment site (Zempsky, 2008).

Low-frequency ultrasound produces gaseous cavities in a liquid medium, a process known as acoustic cavitation which can disrupt lipid bilayers in the stratum corneum to accelerate transdermal passage of drugs (Mitragotri and Kost, 2004). This technology can be used in conjunction with anaesthetic creams with shorter application times. Sonophoresis followed by a 5 min application of liposomal lidocaine has been evaluated in both adults and children for venous access pain and is superior to no treatment or placebo and equivalent to a 30 min treatment of liposomal lidocaine (Becker et al., 2005; Skarbek-Borowska et al., 2006; Zempsky et al., 2008). Adverse events immediately after ultrasound are limited to redness and mild discomfort.

Lidocaine particles can be delivered painlessly into the skin under pressure. Helium gas when released accelerates lidocaine particles to velocities that are sufficient to penetrate the epidermis and produce local analgesia. Onset of action for venous access procedures is within 1 to 3 min with superiority over placebo in large randomized controlled trials in children. Skin reactions such as erythema, petechiae are short-lived and self-limited (Zempsky, 2008a, 2008b).

Topical anaesthetics can also be used to provide either complete or partial anaesthesia prior to wound repair (Eidelman et al., 2011). The most well studied of these solutions are tetracaine adrenaline and cocaine (TAC) and lidocaine, epinephrine (adrenaline), and tetracaine (LET). Due to the disruption of the epidermis these solutions are easily absorbed into the wound with the vasoconstrictor minimizing diffusion. LET has essentially replaced TAC in the US due to the expense of cocaine as well as drug control and safety issues. LET which can be made by the in-hospital pharmacy as a liquid or gel preparation, provides excellent wound anaesthesia for facial lacerations in 20 to 30 min (Ernst et al., 1995; Schilling et al., 1995). TAC and LET are less effective for extremity wounds and repair of these lacerations often requires supplemental anaesthesia (Singer and Stark, 2001; Zempsky and Karasic, 1997). A Cochrane

Green, Iontophoretic delivery of peptide drugs, pp. 33–48, Copyright © 1996, with permission from Elsevier, <http://www.sciencedirect.com/science/journal/01683659>.

review of topical anaesthetics for wound repair recommended future trials comparing LET to other cocaine-free compounds, as well as further study of in pre-verbal and non-verbal children. Application on or near mucous membranes should be avoided with these compounds to minimize the potential for systemic absorption.

## Topical medications for the treatment of musculoskeletal and neuropathic pain

While indicated for the treatment of postherpetic neuralgia in the US, lidocaine 5% topical anaesthetic patch (Lidoderm®, Endo Pharmaceuticals, Chadds Ford, PA) has gained usage in a variety of clinical conditions both neuropathic and musculoskeletal. A 5% lidocaine patch is composed of an adhesive material containing that is applied to a non-woven polyester felt backing which allows for slow release of lidocaine. The patch provides analgesic action, reducing pain with some decrease in sensory function but without the complete loss of sensation thus it is not effective for procedural pain (Krumova et al., 2012; Wehrfritz et al., 2011). The size of the patch is 10 cm × 14 cm (Galer, 1999).

In addition to treatment of postherpetic neuralgia, the 5% lidocaine patch has been used with efficacy in a variety of neuropathic pain conditions such as post-thoracotomy pain, complex regional pain syndrome, and post amputation pain (Devers and Galer, 2000). The lidocaine patch is also effective for musculoskeletal conditions. The 5% lidocaine patch has been shown to be effective in adults with osteoarthritis (Galer, 2004a; Gammaaitoni, 2004) and with lower back pain (Galer et al., 2004b; Gimbel et al., 2005). The lack of significant side effects makes topical 5% lidocaine an appropriate option in adults for any focal neuropathic pain with allodynia or hyperalgesia (Jensen et al., 2009). The patch must be placed at the site of pain in order to be effective.

While it has not been studied specifically in children we have used it successfully in many of the conditions described previously, especially lower back pain and focal neuropathic pains. Lidocaine absorption in adult usage amounts to only 3% to 5% of the total dose available in the patch and systemic levels do not increase with daily use, and systemic toxicity in adults is felt not to be a significant risk (Campbell et al., 2002; Lidoderm Package Insert, n.d.). For children under 50 kg we limit the treatment to one to two patches for 12 h per day to insure safety. Children over 50 kg can use the adult dose of three patches for 12 h per day. Often 7 to 10 days of

treatment is necessary before efficacy is noted. Side effects are usually limited to redness or other signs of skin irritation.

Topical NSAIDs can provide local relief without the risks of an orally or parenterally delivered NSAID. They have primarily been evaluated for osteoarthritis and acute musculoskeletal injury. These drugs are applied over the injured or painful body part and penetrate into the subcutaneous tissues, musculature, and tendons where they exert their therapeutic action (Esparza et al., 2007).

After administration of topical NSAIDs peak plasma concentrations are 0.2% to 8% of concentrations achieved with appropriate oral dosing (Heyneman et al., 2000). However, levels of NSAID in the meniscus and cartilaginous structures as well as in muscular tissues are four to seven times greater after topical administration than oral administration (Bandolier extra, 2005; Tegeder et al., 1995). Concentrations in the tendon sheath are several hundred times greater than plasma concentration after topical administration. Length of time to Cmax is about ten times longer in topically rather than orally administered NSAIDs with Cmax for topical preparations ranging from 2.2 to 23 h (Heyneman et al., 2000).

Unlike orally administered NSAIDs, topical NSAIDs have not been associated with increased risk of bleeding, and the risk of any gastrointestinal side effects for topical administration is considerably lower (Bandolier extra, 2005). Adverse events with topical NSAIDs are predominately local cutaneous reactions. Photosensitivity is a rare adverse reaction to topical NSAIDs (Bandolier extra, 2005).

There are a variety of preparations of topical NSAIDs including creams, gels, patches, and plasters. NSAIDs delivered topically include diclofenac, ketoprofen, and ibuprofen. Superiority of topical NSAIDs compared with placebo has been demonstrated for both diclofenac and ketoprofen patches for acute musculoskeletal conditions (Haroutiunian et al., 2010). Based on a large meta-analysis ketoprofen may be the most effective of the topical NSAIDs for acute pain (Mason et al., 2004). Though there are fewer comparative trials, in general, topical NSAIDs appear as effective and have a better safety profile in adults than oral NSAIDs, though onset of action is slower (Heyneman et al., 2000; Underwood et al., 2008).

Unfortunately there are no randomized trials of topical NSAIDs in the paediatric age group. Given the excellent safety profile and low systemic absorption of topical NSAIDs, utilization of these agents in children and adolescents with acute or chronic musculoskeletal pain is a reasonable option.

Capsaicin, the active compound in chilli peppers, is a counter irritant (a substance applied to the skin which, by acting as an irritant on a painful zone, attenuates the sensation of pain) which provides some relief in neuropathic pain conditions. Capsaicin is a TRPV1 agonist that first activates nociceptive nerve fibres in the skin and causes the release of substance P which results in neurogenic inflammation. This is followed by reversible defunctionalization of nerve endings resulting in the inhibition of pain transmission (Derry et al., 2009; Irving et al., 2011; Knoktova et al., 2008).

Low-concentration (0.025% and 0.075%) capsaicin creams have shown mild efficacy in a variety of neuropathic conditions including postherpetic neuralgia, diabetic neuropathy, polyneuropathy, and postsurgical neuropathic pain. These creams must be applied several times a day and can take several weeks of application to have effect (Knoktova et al., 2008). More recently an 8% capsaicin patch has been developed for one-time use and shown efficacy in postherpetic neuralgia and HIV neuropathic pain (Irving et al., 2011). Oral capsaicin has shown some efficacy in reducing mucositis pain in adult cancer patients (Berger et al., 1995).

Local skin irritation with capsaicin cream use is common with burning and erythema and itching are predominant side effects. These effects usually diminish after 1 to 2 weeks of use. Pretreatment of the skin with topical anaesthetic is necessary prior to use of the capsaicin 8% patch to improve tolerability.

Use of capsaicin in paediatrics is limited to case reports. This includes the use of a compounded form of 10% capsaicin in a 9-year-old with erythromelalgia (McElhiney, 2011). Given the rare incidence of systemic side effects, use of capsaicin for neuropathic pain in children and adolescents could be considered and will be limited by tolerance to the application.

Other counter irritants such as methyl salicylates and menthol have also been used for musculoskeletal pain. Methyl salicylate may have direct analgesic effects but also provides tissue warming by its vasodilatory effects (Higashi et al., 2010). Menthol's mode of action is likely the cooling effect it has on the skin. There is limited evidence for the efficacy of these compounds however a recent study of a 10% methyl salicylate 3% menthol patch demonstrated greater pain relief than placebo in 208 adults with muscle strains (Higashi et al., 2010).

The identification of peripheral opioid receptors and the adverse systemic effects of opioids have led to the use of topical opioids primarily in the palliative care setting for ulcers and mucositis (Coggeshall and Carlton, 1997; Lebon et al., 2009). Morphine is the most common opioid reported in the literature although diamorphine, methadone, oxycodone, and meperidine have also been studied. A review of 19 studies (six randomized controlled trials and 13 case reports) found support for efficacy but recommended further larger trials (Lebon et al., 2009). Morphine is used either mixed with intrasite gel to apply to ulcers, or swished and spit as a 1% or 2% mouthwash for mucositis (Cerchiatti et al., 2003; Zeppetella et al., 2003). A case report on the use of topical morphine gel in two adolescents with epidermolysis bullosa reported good efficacy with no side effects despite prolonged use for 4 weeks and 5 months (Watterson et al., 2004).

Ketamine and amitriptyline either alone or in various combinations have been used to provide pain relief in neuropathic pain conditions. The evidence supporting their use is mixed although negative studies may reflect lower concentrations of the agents used. A study of 4% amitriptyline and 2% ketamine demonstrated

reduced pain in adults with postherpetic neuralgia compared with a lower concentration cream or placebo and a randomized controlled trial of 10% ketamine reduced allodynia in adults with complex regional pain syndrome (Finch et al., 2009; Lockhart 2004). In the second trial no systemic ketamine was detected 1 h after application in ten patients (Fisch et al., 2009). For clinical use these preparations may require the expertise of a compounding pharmacist.

Dexamethasone, a steroid, can be delivered iontophoretically for a variety of inflammatory conditions such as medical and lateral epicondylitis, Achilles tendonitis, and plantar fasciitis (Gudeman, 1997; Neeter, 2003; Nirschl, 2003). In the US this procedure is primarily performed by physiotherapists. Unlike lidocaine iontophoresis described earlier, dexamethasone is negatively charged so it must be placed on the negatively charged electrode to facilitate drug delivery. The data supported the efficacy of dexamethasone iontophoresis is variable. The largest study which evaluated dexamethasone iontophoresis for epicondylitis demonstrated reduced pain in the active drug group versus placebo iontophoresis, however the results of several other smaller trials including one for epicondylitis were mixed. It is likely that dexamethasone iontophoresis provides short-term benefits including pain relief in acute musculoskeletal injuries (Torro, 2011).

One paediatric study of dexamethasone iontophoresis demonstrated efficacy in a case series of 28 patients with juvenile idiopathic arthritis treated for temporomandibular joint involvement (Mina, 2011). Side effects in this study and others are similar to those mentioned previously with iontophoresis.

## Conclusion

There are a variety of effective topical medications for both procedural pain as well as musculoskeletal and neuropathic pain. For procedural pain these medications have been well studied in children and their use should be encouraged. There is limited data to support the efficacy of topical medications in the paediatric population for musculoskeletal and neuropathic pain conditions. However, given the excellent safety profile including lack of systemic absorption and minimal local side effects the use of these medications in the paediatric age group should be considered.

### Case example

A 15-year-old girl presents to the chronic pain clinic with a 4-month history of back pain. Her pain is usually a 4 to 6 out of 10 at rest but increases to an 8 to 9 out of 10 with activity. She continues to attend school, has no trouble sleeping, and her mood as reported by her both herself and her mother is good. She does say it is hard to concentrate at school because she has to shift positions multiple times during class to stay comfortable. She is frustrated because she has not been able to participate in dance since her pain started. She has had an extensive workup that includes orthopaedic evaluation, plain films and a magnetic resonance imaging scan of the lumbosacral spine. The radiological studies were normal. She took ibuprofen for several weeks after the onset of pain; however, this was not helpful. She has had eight sessions of physiotherapy focused on core strengthening. She says the physiotherapy has not reduced her pain but that the

electrical stimulation they do during therapy does reduce her pain temporarily.

On physical exam she is a comfortable appearing, pleasant, non-obese female. Notable findings on her exam include paraspinal muscular tenderness and tightening in the lumbar region. She has increased pain with forwards and especially backwards flexion. She has no evidence of hypermobility and her neurological exam is normal.

**Recommendations:** you recommend a lidocaine 5% patch. She should apply it for 12 h daily (usually at night). She should cut the patch in half and place the halves over the areas of maximal tenderness. The patches should be placed in the same location every night. You tell her to give it at least 2 weeks of regular use to expect results (the manufacturer recommends 7 to 10 days for pain reduction from postherpetic neuralgia but our experience for back pain is that it takes a longer period of time).

You also recommend that she obtain a TENS (transcutaneous electric nerve stimulation) unit from her physiotherapist. She can wear this at times during the day when her pain becomes severe. It is also helpful during school classes to help reduce pain and enable her to concentrate.

**Follow-up:** she returns to the clinic 6 weeks later with her pain essentially resolved. She experienced no local irritation or other side effects from the patch. She continues to use the lidocaine patches and has now transitioned from physiotherapy and is doing some low-intensity dancing. You tell her to use the patches for another 2 weeks and return to see you again if her pain returns.

## CHAPTER 48

# Drugs for neuropathic pain

Sachin Rastogi and Fiona Campbell

### Summary

Neuropathic pain is defined as 'pain arising as a direct consequence of a lesion or disease affecting the somatosensory system'. It is often contrasted with nociceptive pain which is associated with tissue injury or inflammation. Neuropathic pain exhibits certain clinical features that differentiate it from nociceptive pain. Neuropathic pain conditions in children are different from those in adults and include complex regional pain syndrome (CRPS), phantom limb pain, postoperative and post-traumatic neuropathic pain, and autoimmune and degenerative neuropathies, e.g. Guillain-Barré syndrome, Charcot-Marie-Tooth disease. However, a lack of randomized controlled trials in children means that evidence from adult studies guides pharmacological management of neuropathic pain in children, which is problematic as the aetiologies and mechanisms are different.

In this chapter we propose an algorithm for drug therapy for neuropathic pain in children based on best available evidence, our clinical experience, and the safety of these drugs in paediatric practice. We suggest a step-wise approach incorporating first-, second-, third-, and fourth-line therapies that should be tried methodically according to effectiveness and side effects. Neuropathic pain in children, if identified and treated in a timely manner as part of an interdisciplinary framework, using multimodal strategies can be managed effectively.

### Introduction

#### Neuropathic pain

The International Association for the Study of Pain (IASP) defines pain as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage' (Merskey and Bogduk, 1994, p. 210). Pain can be categorized in various ways; by (1) its temporal profile (i.e. acute, chronic, recurrent), (2) disease type (e.g. sickle cell pain, cancer pain), or (3) pain mechanism (nociceptive, neuropathic). Neuropathic pain has recently been defined as 'pain arising as a direct consequence of a lesion or disease affecting the somatosensory system' (Treede et al., 2008). Traditionally, pain type is broadly classified into nociceptive and neuropathic. Nociceptive pain is initiated by normal activation of pain pathways by noxious stimuli, whereas neuropathic pain is associated with abnormal activation of pain pathways involving both the peripheral and central nervous system. It is a complex,

partially understood phenomenon with characteristic clinical features, which have predominantly been described in adults. For the purposes of this chapter the term 'children' will refer to all children and adolescents unless indicated otherwise. Though it is well known that children suffer from neuropathic pain, there have been few paediatric studies. Moreover, it is likely that given the differences in nervous system anatomy and physiology between adults and children, as well as different aetiologies of neuropathic pain, there are significant differences in mechanisms and prognoses.

Though basic mechanisms underlying pain transmission are reasonably well understood, neuropathic pain is a complex, interdependent dynamic state, which is likely influenced by multiple factors including aetiology, previous pain experience, and genetic factors. Interindividual variability in chronic pain expression and response to analgesics are known to have a genetic basis, which may guide future treatments (Sorge et al., 2012), including those for neuropathic pain. Translation of these mechanisms into drug therapy has not been simple, further complicated by the fact that underlying mechanisms in children are different from those in adults. Examples include the increased plasticity of the developing nervous system and altered response to injury, and the reduced spinal microglial response to nerve injury during earlier stages of development (Moss et al., 2007; Vega-Avelaira et al., 2007; see also Vega-Avelaira and Beggs, Chapter 7, this volume). One could postulate that these differences might improve the prognosis of neuropathic pain in children.

#### Clinical features

Neuropathic pain is characterized by positive symptoms and negative symptoms (sensory loss, numbness). Positive symptoms are either spontaneous pains that can be (1) continuous (e.g. burning, throbbing) or intermittent (e.g. shooting, stabbing) or (2) evoked (e.g. hyperalgesia and allodynia). Hyperalgesia is defined as 'increased pain from a stimulus that usually provokes pain' and allodynia as 'pain due to a stimulus that does not normally provoke pain' (Merskey and Bogduk, 1994). Positive symptoms may be understood in terms of pathological changes in the peripheral nerves, as a way in which the nervous system attempts to compensate for sensory loss. A high index of suspicion is required to make a diagnosis of neuropathic pain, and an early clue is the poor response to simple analgesics such as acetaminophen and non-steroidal anti-inflammatory drugs. Diagnosis is presently based upon the history comprising qualitative pain descriptors and basic neurological

examination. Common pain descriptors include burning, throbbing, electrical, stabbing, shooting, pricking, and pins and needles. In addition to positive and negative symptoms, autonomic dysfunction can sometimes be seen (e.g. vasomotor, sudomotor, and trophic changes), particularly in the context of complex regional pain syndrome (CRPS) (see Clinch, Chapter 24; Vega-Avelaira and Beggs, Chapter 21; Walker, Chapter 7, this volume).

Neuropathic pain: children versus adult

Neuropathic pain in adults affects up to 8% of the population with significant impact on quality of life (Torrance et al., 2006); no epidemiological data exists regarding prevalence in children (Walker, 2008). This might in part be due to a lack of an agreed definition and diagnostic criteria for paediatric neuropathic pain. In addition, compared to adults, the common causes of neuropathic pain in adults are rare in children. Diabetic neuropathy, trigeminal neuralgia, postherpetic neuralgia (PHN) (Hempenstall et al., 2005) and central post-stroke pain are conditions that seldom affect children, but are major causes of neuropathic pain in adults. Moreover, most of the adult literature from which paediatric neuropathic pain management is extrapolated is based on common adult aetiologies. Causes of neuropathic pain in children are heterogeneous (Walco et al., 2010) (Table 48.1). According to the latest definition of neuropathic pain for adults (Treede et al., 2008)—CRPS type 1 would not fit into the classification as there is no evidence of direct nerve disease or injury. However, given its frequency and response to anti-neuropathic pain medications, CRPS type 1 in children will be considered in this chapter.

With clearer diagnostic instruments for paediatric neuropathic pain, and improved recognition and understanding, it is likely that the prevalence in children is more than we would like to think. Neuropathic pain is often part of a mixed picture alongside nociceptive pain, for example, vaso-occlusive pain in sickle cell disease (Niscola et al., 2009).

A paucity of randomized controlled trials (RCTs) in children, a lack of validated neuropathic pain scales in children, uncertainty over definitions of neuropathic pain and diagnosis has led to a lack of data and over-reliance on extrapolation of adult studies, case reports and expert opinion (Level 4). For these reasons many of the drugs described are used off-licence.

Drugs

The drugs used in the symptomatic management of neuropathic pain in children are presented in a step-wise, practical manner, based on our clinical experience in paediatric practice, the implications of committing children to certain therapies, and best quality evidence (Levels 1 and 2). The evidence comes from adult studies as very few clinical trials have been conducted in children with neuropathic pain, and the literature is predominantly case series or isolated case reports. With inadequate or partial pain relief, additional drugs can be added in combination (with exceptions noted in the text—see Table 48.2 for detailed dosing and side effect information for first-, second-, and third-line medications).

First-line agents

Tricyclic antidepressants

Tricyclic antidepressants (TCAs) such as amitriptyline and nortriptyline are commonly used to treat neuropathic pain, with

Table 48.1 Causes of neuropathic pain in children

Causes of neuropathic pain in children	Specific examples
<b>Peripheral causes</b>	
Postsurgical pain	Pain after amputation
	Postoperative neuropathic pain
Complex regional pain syndrome	Type 1 (without nerve injury)
	Type 2 (with nerve injury)
Plexus injuries	Congenital
	Traumatic
Childhood cancer	Tumour related
	Treatment related
Autoimmune neuropathy	Guillain–Barré syndrome
Hereditary neurodegenerative disorders	Fabry disease
	Charcot–Marie–Tooth disease
Toxic and metabolic neuropathies	Lead, mercury, alcohol
Infection	(HIV)
Mitochondrial disorders	
Erythromelalgia	Primary
	Secondary
Burns	
Haematological	Sickle cell disease
<b>Central causes</b>	
Spinal cord injury	Congenital
	Traumatic
Brain	Traumatic
	Tumour

a proven track record over time (Finnerup et al., 2005; Saarto and Wiffen, 2005). The mechanism of action of TCAs in neuropathic pain is separate from its mode of action in depression (Max et al., 1987). This is reflected in the lower doses required for neuropathic pain. The multimodal mechanism of action comprises blockade of serotonin and noradrenaline reuptake, interaction with sodium and calcium ion channels, as well as some antihistamine and anticholinergic antagonism. The onset of pain relief is generally quicker (1–2 weeks) than its antidepressant effect. The metabolism of TCAs is dependent upon cytochrome P450 (CYP) metabolism (CYP2D6) and susceptible to genetic polymorphism. Therefore, in ‘poor metabolizers’ (up to 25% of the population) an increase in plasma levels can be seen (Lotsch and Geisslinger, 2006).

There are no published RCTs in children. In adults, the NNT (number needed to treat) for TCAs in neuropathic pain is just over 2. This equates to roughly one in every two patients receiving a 50% reduction in pain with a TCA (Finnerup et al., 2005, 2010). Studies looking at the efficacy of TCAs in neuropathic pain have looked at adults with a range of ‘classic’ neuropathic pain conditions such as PHN, painful neuropathies, traumatic nerve injury, and trigeminal neuralgia (Saarto and Wiffen, 2005).

**Table 48.2** Commonly used first-, second-, and third-line drugs; dosages and side effects

Drug group	Drug name	Dose	Side effects
<b>First line</b>			
TCA	Amitriptyline	<50 kg: 0.1 mg/kg PO QHS, increase as tolerated every 4–6 days by 0.25 mg/kg increments until good analgesia occurs, limiting side effects or to a max of 0.5–2 mg/kg. Decrease by same rate if unhelpful. >50 kg: start at 10 mg, increase as tolerated by 10 mg increments every 4–6 days until a maximum of 75 mg. Decrease by same rate if unhelpful	Sedation, dry mouth, blurred vision, urinary retention, tachycardia, constipation, prolongation of QTc interval, orthostatic hypotension
	Nortriptyline	See above	See above
$\alpha_2$ - $\delta$ ligand	Gabapentin	<50kg: Day 1: 3–5 mg/kg PO QHS Day 2: 3–5 mg/kg BID Day 3: 3–5 mg/kg TID Escalate more slowly if required Maintenance 20–30 mg/kg/day TID	Sedation, dizziness, caution in renal failure
		>50kg and adolescents: Day 1: 300 mg PO QHS Day 2: 300 mg BID Day 3: 300 mg TID Escalate dose as tolerated until good analgesia, limiting side effects or a maximum dose of 3600 mg/day. Additional benefit may not be seen beyond 2400 mg/day	
		Decrease by same rate if unhelpful.	
	Pregabalin	<50kg: 1–2 mg/kg/day PO BID. Titrate upwards weekly to effect >50kg: start at 75 mg PO BID.	See above
		Titrate upwards weekly to effect, to a maximum dose of 600 mg BID	
		Decrease by same rate if unhelpful.	
Topical	Lidocaine 5% patch	Each plaster or patch is applied over intact, dry and non-irritated skin for a period of 12 h on and 12 h off. A maximum of 3 plasters is recommended at any one time	Skin irritation
<b>Second line</b>			
SSNRI	Duloxetine	>50 kg: starting dose 30 mg PO daily for 1 week before increasing to 60 mg	Dry mouth, sedation, dizziness, loss of appetite, nausea, constipation
	Venlafaxine	1–2 mg/kg per day divided BID or TID increased weekly to a maximum of 225 mg/day	See above, prolongation of QTc interval
Topical	Capsaicin	Can be administered in the form of creams, lotions and patches in a range of 0.025–8% by weight. 8% capsaicin patch involves a single 60 min application with up to 12 weeks of effective subsequent analgesia in adults	Initial local burning discomfort
<b>Third line</b>			
Weak mu opioid receptor agonist	Tramadol	1–3 mg/kg PO every 6 h Also available in extended-release 12 h formulation, and in combination with acetaminophen (Tramacet™)	Nausea, vomiting, pruritus, constipation, hallucinations, sedation
Opioid	Morphine	Initial 0.2–0.5 mg/kg PO every 4 h PRN. After 2 weeks convert total daily dose to long-acting preparation and keep short-acting preparation for breakthrough. No ceiling effect; dose escalation can proceed with careful titration, but at high daily doses (180 mg), efficacy should be re-assessed and opioid switch or alternative options considered. An adequate trial should last between 4–6 weeks; and discontinued if there is no improvement in pain or function	Nausea, vomiting, pruritus, constipation, hallucinations, sedation, dry mouth, respiratory depression, urinary retention, caution in hepatic and renal failure, tolerance, dependence, addiction, opioid-induced hyperalgesia, immunosuppression, endocrine dysfunction (infertility)
	Oxycodone	Initial 0.1–0.2 mg/kg PO every 4–6 h as needed. After 2 weeks convert to long-acting preparation, and keep short acting dose for breakthrough	See above
Cannabinoid	Nabilone	<50 kg: 10 mcg/kg PO BID >50 kg: 1 mg BID	Sedation, dizziness, nausea, vomiting

BID = twice daily; PO = orally; QHS = every night at bedtime; TID = three times daily.

TCAs confer additional advantages in that they are inexpensive, have once-daily dosing, and can be helpful for patients in whom sleep is a problem. Side effects of TCAs are predominantly anticholinergic and antihistaminic (Table 48.2). Cardiac toxicity is a concern due to the risk of prolongation of the QTc interval, and there have been case reports of sudden death in children with arrhythmias (Varley, 2001). While there is currently no published evidence-based guideline, it is our practice for every child to have a baseline electrocardiogram (ECG) to rule out conduction abnormalities before commencing a TCA. Adverse effects can be minimized by starting the TCA at a low dose at night (see Table 48.2).

Most experience of TCAs in children is with nocturnal amitriptyline since sedation is common and this can be capitalized upon to aid sleep. Nortriptyline is similar to amitriptyline but is a secondary amine so exhibits fewer side effects.

Desipramine, another TCA, is no longer used in children following several reports of sudden death (Biederman et al., 1995). Should TCAs not be helpful, they should be weaned slowly and not stopped abruptly. Children should be advised that vivid dreams may occur as the drug is tapered.

### Alpha-2-delta ligands

The alpha-2-delta ( $\alpha_2\text{-}\delta$ ) ligands, sometimes referred to as gabapentinoids (gabapentin and pregabalin), are effective treatments in many forms of neuropathic pain (Backonja et al., 1998; Freynhagen et al., 2005; Rowbotham et al., 1998; Serpell, 2002). Gabapentin binds to voltage-gated calcium channels at the  $\alpha_2\text{-}\delta$  subunit (Gee et al., 1996), as well as modulating gamma-aminobutyric acid (GABA) synthesis, release, and metabolism. Gabapentin and pregabalin are lipophilic analogues of GABA which interact with the  $\alpha_2\text{-}\delta$  subunit common to all voltage-gated calcium channels, which explains their therapeutic effect in neuropathic pain. There is evidence to suggest that these drugs selectively target those calcium channels that display abnormal activity (Li et al., 2006), as well as evidence of  $\alpha_2\text{-}\delta$  upregulation with nerve injury (Boroujerdi et al., 2011; Luo et al., 2002).

Gabapentin has been used extensively in paediatric practice (Golden et al., 2006). Though it has been superseded by other anticonvulsants in the treatment of epilepsy, its use in paediatric neuropathic pain is now established. There have been numerous case reports and series in paediatric neuropathic pain and CRPS (McGraw and Kosek, 1997; Rusy et al., 2001; Wheeler et al., 2000), as well as strong evidence from the adult literature to support its use. Gabapentin has also been successfully used in neurologically-impaired children with unexplained (neuro) irritability, improving behaviour and pain scores, which has contributed to the familiarity of the drug in paediatrics (Haney et al., 2009; Hauer et al., 2007).

There is less experience with pregabalin than gabapentin in the treatment of paediatric neuropathic pain. Pregabalin is effective in adults (Freynhagen et al., 2005), but there is no strong evidence that it is any better than gabapentin. There is limited evidence to support its use in children (Vondracek et al., 2009). Pregabalin demonstrates a similar efficacy and side effect profile to gabapentin; however, it has the advantage of twice daily (BID) dosing. In adults, pregabalin has been licensed for generalized anxiety disorder, painful diabetic neuropathy, and been shown to be effective in fibromyalgia. The increased cost of pregabalin in some countries might make it prohibitive and favour gabapentin as a first-line treatment.

### Topical lidocaine 5% plasters (patches) (see also Zempsky, Chapter 47, this volume)

The purported mode of action is due to the local anaesthetic action of lidocaine, which stabilizes neuronal membranes causing down-regulation of sodium channels (Rosielle, 2008).

Topical lidocaine 5% medicated plasters provide an alternative pharmacological non-systemic option in the treatment of neuropathic pain with good evidence in adults supporting its use in herpetic neuralgia (Binder et al., 2009) and focal peripheral neuropathy (Meier et al., 2003). Lidocaine plasters are also effective in combination with other antineuropathic analgesics and reduction in co-analgesic consumption was demonstrated in a retrospective observational study in adults. Their efficacy in children for neuropathic pain is supported by case series (Nayak and Cunliffe, 2008).

Systemic absorption of lidocaine is very low so side effects are minimal and therefore advantageous for children. Additional benefit comes from the patch providing a physical barrier to painful touch and a cool sensation from the patch itself. It is applied for 12 h followed by 12 h off over the focal painful area. Cost can be prohibitive in some countries, and it is not licensed for use in many countries, e.g. Canada. A less expensive 5% lidocaine gel is also available and is effective in PHN (Rowbotham et al., 1995).

### Second-line agents

#### Selective serotonin and noradrenaline reuptake inhibitors

Balanced selective serotonin and noradrenaline reuptake inhibitors (SSNRIs) such as duloxetine and venlafaxine cause an increase in serotonin and noradrenaline, which work either presynaptically to reduce nociceptive transmission or postsynaptically to increase endogenous spinal inhibition (Smith, 2006). SSNRIs are predominantly used as antidepressants, although the analgesic mode of action is independent of the antidepressant effect.

Duloxetine has proven efficacy in painful diabetic polyneuropathy (Wernicke et al., 2006), depression, generalized anxiety, and fibromyalgia (Hauser et al., 2009) in adults. However, the role of duloxetine in paediatric neuropathic pain is not clear. Venlafaxine also has well-documented efficacy in painful diabetic polyneuropathy (Rowbotham et al., 2004), but not PHN in adults (Grothe et al., 2004). SSNRIs cannot currently be recommended as first-line treatments in paediatrics, and should only be used as a second-line agent if there is a contraindication to or failure of TCAs. According to the adult literature, selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine and citalopram are poorly effective in neuropathic pain which may partially be explained by a predilection for facilitatory serotonin (5-HT)-3 receptors by SSRIs rather than inhibitory 5-HT1 receptors (Mattia et al., 2002); however, more good quality trials are needed. As it stands, there is little to suggest that they are more effective than TCAs, so their use in neuropathic pain is currently not recommended.

SSNRIs do not have anticholinergic effects so have an improved side effect profile compared to TCAs in adults. Duloxetine appears to be safe from an adverse cardiac conduction effect in adults (Wernicke et al., 2007). Venlafaxine has been linked with cardiac conduction abnormalities and increases in blood pressure, so a baseline ECG and blood pressure monitoring is recommended (Rowbotham et al., 2004). SSNRIs should not be used in conjunction with a TCA, given the risk of precipitating serotonin syndrome. When discontinuing SSNRIs the dose should be tapered to avoid a withdrawal response.

### Topical capsaicin cream (see also Zempsky, Chapter 47, this volume)

Capsaicin is derived from chilli pepper and has been used for its medicinal properties for over 150 years. Its mechanism of action was originally thought to be due to depletion of substance P at peripheral nerve endings, though this does not fully explain its analgesic action. Capsaicin has a complex mechanism of action; it activates the transient receptor potential vanilloid 1 (TRPV1) receptor which initially results in sensory neuronal depolarization causing burning and itching, but over time leads to localized 'defunctionalization' of cutaneous nociceptors and analgesia (Anand and Bley, 2011).

Low-concentration formulations of capsaicin are supported by modest evidence but require daily application which may limit its use in children (Derry et al., 2009). The newer high concentration preparation 8% capsaicin patch (Qutenza™) has been used with success in adults with focal peripheral neuropathic pain (Backonja et al., 2008). It should be considered as a second-line topical intervention in children with focal neuropathic pain where lidocaine patches are either unavailable or have failed to show improvement in symptoms after an adequate trial.

Topical capsaicin is available in a variety of strengths and formulations to manage pain (Table 48.2). Although it is generally safe in terms of toxicity, the initial burning discomfort with application can result in problems with compliance, especially in children. These problems usually diminish with time, but the drug can take up to 4 weeks to produce benefit, requiring considerable patience in young patients. The newer stronger 8% capsaicin patch involves a single 60 min application with up to 12 weeks of effective subsequent analgesia. Pretreatment with a topical anaesthetic agent (e.g. EMLA®) may help with compliance, but its efficacy in children is not yet known.

### Third-line agents

#### Tramadol

Tramadol has a unique dual mode of action whereby it inhibits the reuptake of central serotonin and noradrenaline as well as being a weak mu receptor agonist (five to eight times weaker than morphine). This unique mechanism of action may explain its efficacy in neuropathic pain.

Tramadol is effective in adults with PHN (Boureau et al., 2003) and painful diabetic neuropathy (Harati et al., 1998; Sindrup et al., 1999). A Cochrane review demonstrated its usefulness in neuropathic pain with a NNT of 3.5 (Hollingshead et al., 2006).

Tramadol is often seen as occupying a middle ground before starting a pure opioid agonist. The abuse potential of tramadol is thought to be less than that of opioids in adults (Cicero et al., 2005). Caution is required when combining tramadol with a TCA, SSNRI, or SSRI, given the risk of precipitating serotonin syndrome. This may not be an issue when tramadol is combined with low-dose TCA (e.g. amitriptyline 10 mg). Tramadol is metabolized by the CYP enzyme system (CYP2D6) and is therefore susceptible to genetic polymorphism and variable pharmacokinetics (e.g. poor metabolizers). Such variation in response to tramadol may be reduced by the introduction of the new similar compound tapentadol, which neither requires metabolic activation nor is dependent on isomer-related pharmacodynamics. However, RCTs in neuropathic pain are lacking and as such the use of tapentadol in children cannot currently be recommended.

### Opioids

The term opioid refers to any compound synthetic or natural that activates the mu receptor; opiates specifically refer to drugs which derive directly from *Papaver somniferum*. Central inhibitory systems are the site of action of opioids which are agonists at inhibitory opioid receptors found in the brain, spinal cord, and periphery (see Hathway, Chapter 44, this volume); the action of endogenous opioid peptides is much less than that seen with opioid drugs.

The historical dogmatic view that opioids do not demonstrate efficacy in neuropathic pain has long been refuted. Opioids have shown consistent analgesic efficacy in treatment of neuropathic pain (Eisenberg et al., 2006), especially supporting the use of morphine, oxycodone (and tramadol), and have considerably faster onset of action compared to other agents. Little evidence exists to favour the use of fentanyl, buprenorphine, or meperidine in neuropathic pain ahead of other opioids, so will not be discussed further. We do not use codeine in children at our institutions due to unpredictable analgesic effects and significant adverse effects caused by its genetic polymorphism (Ciszkowski et al., 2009; Madadi and Koren, 2008). Problems surrounding the use of opioids relate not to their efficacy but to both their short- and long-term side effects, especially when used in children (Table 48.2). Long-term effects on sexual hormone production (Katz and Mazer, 2009) and immune function (Vallejo et al., 2004) have significant implications for children. For this reason opioids are not considered first- or second-line treatments for neuropathic pain in children, unless the pain is acutely severe or in neuropathic cancer pain. Before committing a child to opioid therapy, risk factors for abuse should be screened including previous substance abuse, history of psychiatric disease, and family history of drug abuse (National Opioid Use Guideline Group (NOUGG), 2010; Zacny et al., 2003). Particular care is required when treating adolescents. We advocate using an opioid contract system when initiating therapy; we include a generic example of a contract for children and adolescents (see Figure 48.1) based on NOUGG recommendations (NOUGG, 2010).

#### Morphine

Morphine is the gold standard opioid and the one with which most practitioners treating children have most experience. It is a natural derivative of *Papaver somniferum* (opium poppy).

Morphine is the prototypical mu receptor agonist, given orally its bioavailability is low (30%) and duration of action is 3 to 5 h, or 12 h if using a sustained-release preparation. It is metabolized in the liver to morphine 3-glucuronide (M3G) and morphine 6-glucuronide (M6G); the latter is a more potent analgesic than morphine itself. Both M3G and M6G are renally excreted and morphine should be used with caution in patients with any degree of renal insufficiency (see Strassels, Chapter 45, this volume).

Morphine is effective in peripheral neuropathic pain and mixed neuropathic pain in adults (Eisenberg et al., 2006), with particular evidence in painful diabetic neuropathy, PHN, and phantom limb pain (Dworkin et al., 2007). It has been shown to be as effective as gabapentin in one trial (Gilron et al., 2005).

Morphine is a versatile drug which can be administered via a number of routes. For chronic neuropathic pain, the oral route is typically used. Both short-acting and long-acting oral preparations are available, in addition to injectable forms. If the decision is made to discontinue opioid therapy, it should be carefully tapered under medical supervision to avoid withdrawal.

**Patient/Family/Health Care Team Agreement for Opioid Therapy**

**History**

1. Family history of substance use (alcohol, illicit drugs, prescription drugs)  
If yes, please describe:

yesno

2. Personal history of substance use (alcohol, illicit drugs, prescription drugs):  
If yes, please describe:

yesno

3. Age of first alcoholic drink?

4. Have you ever passed out/blacked out?

yesno

5. Psychiatric History:

a. Self harm

yesno

b. Intentional overdose

yesno

c. Suicide attempts

yesno

d. Trauma/abuse

yesno

6. Have you ever been diagnosed with:

a. Depression

yesno

b. Anxiety

yesno

7. Education History:

a. Learning disability

yesno

b. ADD/ADHD

yesno

8. History of sleep apnea

a. Snoring

yesno

b. Sleep study positive

yesno

9. Using sedating medications

yesno

If yes, please list:

**Side Effects:**

Opioids can help pain but they can also have side effects. These may include:

- Sleepiness, confusion, dizziness
- Decreased breathing
- Constipation
- Nausea and/or vomiting
- Itchiness
- Difficulty urinating

I understand to let my team know if I experience any of these side effects.

**Goals of Opioid Therapy:**

I understand that the goals of opioid therapy are:

1. Improve function (such as school attendance, physical activity, seeing friends).
2. Decrease pain scores by at least 30% (eg. from 10/10 to 7/10)
3. Personal goal(s):

I further understand that if the above goals are not achieved within 4 weeks of starting therapy this therapy will be considered unhelpful and adjusted or discontinued. Our team will work together with you to wean this medication gradually to avoid negative effects/withdrawal.

Opioid therapy will be reviewed at least once a month and adjustments made as needed.

Figure 48.1 An example of an opioid contract for children and adolescents.

**Agreement:**

I understand that I am receiving opioid medication from Dr. \_\_\_\_\_ to treat my chronic pain condition. I agree to the following:

1. I/my child will not seek opioid medications from another physician. Only Dr. \_\_\_\_\_ will prescribe opioids for me/my child. In exceptional circumstances (such as my doctor's absence) other anesthesiologists in the Sick Kids pain clinic may prescribe.
2. I/my child will not take opioid medications in larger amounts or more frequently than is prescribed by Dr. \_\_\_\_\_.
3. I/my child will not give or sell my medication to anyone else, including family members; nor will I/my child accept any opioid medication from anyone else.
4. I/my child will not use over-the-counter opioid medications such as 222's and Tylenol® No. 1.
5. I understand that if my/my child's prescription runs out early for any reason (for example, if I lose the medication, or take more than prescribed), Dr. \_\_\_\_\_ may not prescribe extra medications for me; I will have to wait until the next prescription is due.
6. I/my child will not stop the opioid medication suddenly, as this may cause withdrawal.
7. I will fill my/my child's prescriptions at one pharmacy of my choice; pharmacy name: \_\_\_\_\_
8. I will store my medication in a secured location.
9. I agree to monitor for side effects of opioids (such as itchiness, nausea/vomiting, constipation, sleepiness/lethargy) and notify the chronic pain team if they are present.
10. I will not drive when starting or increasing the dose of opioids, and will discuss my ability to drive with Dr. \_\_\_\_\_ prior to driving.
11. I/my child agree(s) to provide a urine sample upon request for opioid screening purposes.
12. I understand that if I break these conditions, Dr. \_\_\_\_\_ may choose to cease to write opioid prescriptions for me.

Patient's signature: \_\_\_\_\_

Parent/Guardian signature: \_\_\_\_\_

Physician/Advanced Practice Nurse signature: \_\_\_\_\_

**Figure 48.1** (Continued)

### Oxycodone

Oxycodone is a semisynthetic opioid which is 1.5 to 2 times the potency of morphine. It exerts its analgesic effect through both mu and kappa agonism, which has been suggested for its efficacy in neuropathic pain (Nielsen et al., 2007). It has a higher oral bioavailability than morphine at 75% due to minimal first-pass metabolism. It is demethylated to noroxycodone and oxymorphone by hepatic CYP2D6, both of which are less active than oxycodone, and then conjugated to inactive glucuronides. Oxycodone has a comparable effect to morphine in neuropathic pain in adults. It has an NNT of 2.6, which means that 1 in every 2.6 patients with neuropathic pain will get a 50% reduction in neuropathic pain with oxycodone (Finnerup et al., 2005). It is available orally as immediate release (4–6 h) and modified release (OxyContin™ 12 h), in addition to preparations combined with acetaminophen (Percocet™) and naloxone (Targin™). Generally speaking we do not support the use of combination analgesics, as the presence of acetaminophen can prevent the upward titration of the opioid analgesic. Parenteral preparations are also available. Unfortunately, oxycodone is one of the most abused opioids in North America, and carries a stigma which may limit its use amongst children (Sproule et al., 2009). When switching from another opioid, it is important to be cognizant of the phenomenon of *incomplete cross-tolerance* whereby a less than equianalgesic dose is required of the second opioid. We recommend converting to a dose of two-thirds of an equianalgesic dose of the second opioid with generous breakthrough analgesia until steady state is reached.

### Methadone

Methadone is a synthetic opioid with multiple mechanisms of action making it unique amongst opioids. Originally used for opioid addiction and dependence, methadone is now used for neuropathic pain, particularly for palliative cancer pain management in adults. It comes as a racemic mixture which consists of S- and D-methadone. It has more affinity than morphine for delta receptors and less for mu receptors. It is also a N-methyl-D-aspartate (NMDA) receptor antagonist as well as noradrenaline and serotonin reuptake inhibitor, which may explain its effectiveness in the treatment of neuropathic pain. Methadone is metabolized in the liver by the CYP enzyme family (CYP3A4, CYP1A2, and CYP2D6) to inactive metabolites. Individual pharmacogenetics may therefore go some way to explain the variation in response to the drug. It is excreted via the faecal route and does not accumulate in renal failure (Layson-Wolf et al., 2002).

In adults, methadone has significantly better efficacy than placebo in mixed neuropathic and nociceptive pain (Morley et al., 2003); however, whether it is better than other opioids is not certain. Theoretically, the additional NMDA antagonism of methadone suggests that neuropathic pain should respond better than other opioids but a Cochrane review has not demonstrated additional efficacy of methadone over other opioids in either cancer pain or neuropathic pain within that population (Nicholson, 2007). More trials are needed as anecdotally methadone is perceived to have additional benefit than other opioids in recalcitrant neuropathic pain.

Methadone is usually taken orally once a day, has a high bio-availability (80%), and accumulates with chronic use. The half-life is unpredictable: 12 to 18 h after a single oral dose, and 10 to 75 h after chronic use. In general, the half-life of methadone increases with patient age. Methadone is approximately five to ten times more potent than morphine; however, conversion ratios depend on the pre-switch opioid dose. The general principle of conversion is that the higher the opioid dose, the lower the conversion ratio, and when commencing methadone to 'start low and go slow'. Care should be taken when combining methadone with a TCA, SSNRI, or SSRI due to its effect on serotonin and noradrenaline reuptake. SSRIs also decrease methadone metabolism and increase plasma levels. Carbamazepine and phenytoin interact with methadone by lowering plasma levels by up to 50%. High doses (>200 mg) can result in torsades de pointes, and methadone should only be prescribed by an experienced specialist physician.

### Cannabinoids

Cannabinoids represent a relatively new pharmacological option as part of a multimodal treatment plan for the management of neuropathic pain (Lynch and Campbell, 2011). With the increasing knowledge of the endocannabinoid system and compelling preclinical work indicating that cannabinoid agonists are analgesic there is increasing attention on their potential role in the management of neuropathic pain. There are no studies in children, but a systematic review of randomized trials of cannabinoids for the treatment of adults with chronic non-cancer pain concluded that cannabinoids are safe and modestly effective in neuropathic pain (Lynch and Campbell, 2011). There were no serious adverse effects reported. Adverse effects that were reported were generally well tolerated, mild to moderate in severity and led to withdrawal from the studies in only a few cases. Cannabinoids studied included smoked cannabis, oromucosal extracts of cannabis-based medicine, nabilone, dronabinol, and a novel tetrahydrocannabinol (THC) analogue. Given that safety and effectiveness have not been established in patients younger than 18 years of age, caution is recommended in prescribing cannabinoids to children predominantly because of psychoactive effects. In practice we recommend the use of nabilone titrated from a very low dose at night (0.005 mg/kg)—and increased to 0.025 mg/kg BID. Nabilone can be compounded—we have used it in very young children through to adolescents. Empirically about one-third of the children obtain some benefit, one-third obtain benefit but limited by side effects, and one-third do not obtain benefit.

### Fourth-line agents

#### Ketamine

Ketamine, an anaesthetic agent and analgesic, is a phencyclidine derivative that can be administered orally, parenterally, topically, intranasally and via the intrathecal or epidural route for neuropathic pain. As an analgesic, ketamine has been used extensively in cancer pain and refractory neuropathic pain, usually as an adjuvant with opioids. Side effects include unpleasant psychomimetic effects, confusion, dysphoria, hallucinations, tachycardia, and hypertension. These adverse effects are usually dose dependent and less pronounced in the lower doses required for analgesia. There is considerable experience with the use of ketamine in children, and the psychomimetic effects appear to be reasonably

well tolerated. Ketamine is usually presented as a racemic mixture of two enantiomers: S(+)-ketamine and R(−)-ketamine. The S(+) enantiomer alone formulation is available in some countries. Ketamine mediates analgesia primarily through non-competitive antagonism at the NMDA receptor at the spinal cord and within the CNS. Reduction in presynaptic release of glutamate may also explain some of the analgesic effect. The S(+) enantiomer has three to four times greater affinity for the NMDA receptor and therefore provides greater analgesia than the R(−) enantiomer at equipotent doses. Ketamine also has a weak effect on opioid receptors, not antagonized by naloxone, as well as antagonistic effects on muscarinic, nicotinic, and monoaminergic receptors. It also exhibits local anaesthetic properties possibly by blocking neuronal sodium ion channels (Bergman, 1999).

Ketamine is metabolized in the liver to norketamine which has a lower anaesthetic potency but greater analgesic potency than ketamine. Oral ketamine therefore is a more potent analgesic than parenteral. Norketamine is then hydroxylated and conjugated by CYP enzyme system in the liver before being excreted via the kidneys.

Systematic reviews of intravenous (IV) ketamine as an adjuvant to opioid analgesia have failed to show a clear benefit in acute peri-operative pain (Bell et al., 2005; Elia and Tramer, 2005). IV ketamine infusions may relieve neuropathic pains of different origins, including PHN (Sang, 2000), peripheral neuropathy, and refractory neuropathic pain syndromes, including CRPS in adults (Schwartzman et al., 2009; Sigtermans et al., 2009). Topical ketamine (see also Zempsky, Chapter 47, this volume) can be effective for allodynia in CRPS type 1 (Finch et al., 2009). Studies in children with neuropathic pain are limited to case reports (Takahashi et al., 1998), with successful use in opioid-refractory cancer pain (Klepstad et al., 2001). Ketamine is not currently recommended as a frontline treatment for neuropathic pain in children as the racemic preparation is hampered by problematic side effects and more trials are needed.

Dosage (for analgesia): 0.1 to 0.5 mg/kg PO every 6 h, can be titrated upwards by 0.1 mg/kg per dose. For weight greater than 50 kg the usual oral dose range is 10 to 100 mg every 6 h, and by IV infusion is: 0 to 0.25 mg/kg/h.

### Intravenous lidocaine infusion

Lidocaine works by blocking conduction of sodium ion channels to reduce spontaneous action potentials in nerve cells. The analgesic properties of IV lidocaine outlast its pharmacokinetic predicted half-life, and analgesia can last for many weeks after a single infusion (Carroll, 2007).

IV lidocaine has been used with success to treat not only neuropathic pain in adults but also CRPS types 1 and 2, cancer pain, and fibromyalgia (McCleane, 2007). An infusion should be administered in a hospital setting with ECG monitoring, but the treatment is generally safe and well tolerated. There is no consensus on infusion dosages or duration but the pharmacokinetic profiles of lidocaine in adults and children are similar; an infusion rate of 1 mg/kg/h has been used with success in children (Wallace et al., 1997). IV lidocaine represents a useful option in the treatment of neuropathic pain in cases refractory to conventional therapy or cases limited by side effects of oral medications. While plasma levels of lidocaine can be measured (levels between 2 and 5 mcg/ml are thought to be therapeutic); we are not aware that this is done

in routine clinical practice. Doses should be adjusted in cases of hepatic and renal insufficiency to avoid toxicity.

### Mexiletine

Mexiletine is an oral type 1b antiarrhythmic agent that is analogous to lidocaine in its mechanism of action. It also acts by blocking sodium channels and has been shown to be of some benefit in adults with painful diabetic neuropathy, though not much superior to placebo (Duby et al., 2004). Its oral preparation is an advantage as opposed to IV lidocaine, however its use in children is limited (Wallace et al., 2000) although there are paediatric case reports of its efficacy in erythromelalgia (Jang et al., 2004; Nathan et al., 2005).

### Other anticonvulsants

Older anticonvulsant drugs such as carbamazepine and phenytoin, typically used in adults with trigeminal neuralgia, have been superseded by newer drugs which are generally safer more effective (e.g. gabapentin). In addition the need for monitoring of liver function with these drugs makes them less appealing in children (Dworkin et al., 2007). The evidence in adults for the use of lamotrigine, oxcarbazepine, valproate, topiramate, lacosamide, and levetiracetam in neuropathic pain has not been convincing, so their place in paediatric neuropathic pain management is uncertain at this time and should only be considered in recalcitrant cases (Finnerup et al., 2010).

### Miscellaneous

Other oral NMDA receptor antagonists such as dextromethorphan, memantine, and riluzide have showed only minor or no improvement in neuropathic pain in adults (Finnerup et al., 2005, 2007), with little experience in children. Magnesium is also an NMDA receptor antagonist that has been shown to be of benefit in neuropathic pain in animal models (Rondon et al., 2010). Its obvious benefit over ketamine is the improved side effect profile, but the drug needs to be given as an IV infusion and further work is required before its role can be fully clarified.

Botulinum toxin A has been used extensively in the treatment of spasticity in children with cerebral palsy (Lukban et al., 2009), and there is emerging data that it may also be effective in neuropathic pain (Francisco et al., 2012). Trials have not shown consistent benefit yet (Dworkin et al., 2010), but familiarity with the drug in children suggests it might have a role.

### Combination strategies

Frequently a single first-line drug is insufficient in alleviating pain to an acceptable level, or side effects become limiting at the higher dose range. In these situations adding in a second agent can provide an additive or synergistic effect to improve analgesia and reduce side effects. The combination of nortriptyline and gabapentin has been demonstrated in an RCT to be superior in neuropathic pain than either drug alone (Gilron et al., 2009). Many RCTs that provide good evidence for combination strategies in adults with neuropathic pain involve opioids as the co-analgesic. The combination of an  $\alpha_2$ - $\delta$  ligand with an opioid has been studied for painful diabetic neuropathy and PHN in adults (Gilron et al., 2005). In fact, morphine was slightly more effective than gabapentin but

the combination provided better analgesia than either drug alone. Combinations of oxycodone and gabapentin have also demonstrated combined improved efficacy at lower dosages than either drug alone (Hanna et al., 2008), however a trial with oxycodone and pregabalin showed no enhanced dual effect (Zin et al., 2010). If based solely on efficacy then opioids would deserve to be second-line treatments for neuropathic pain, however the choice of medication needs to be considered also in terms of potential risks and tolerability, especially in the paediatric population. The relatively improved side effect profile and long-term superior health-related quality of life indices of  $\alpha_2$ - $\delta$  ligands as compared to opioids makes them the better first-line choice.

### Key recommendations

The algorithm in Figure 48.2 is based upon the current literature and our clinical experience in treating neuropathic pain cognizant of risks and long-term effects in children, and extrapolating the best quality evidence from controlled trials in adults with neuropathic pain. This algorithm should be followed in the context of an interdisciplinary approach also incorporating physical and psychological strategies.

After a reasonable trial of 4 to 6 weeks of the selected first-line medication, and only partial analgesia (NRS  $\geq 4/10$ ) or troublesome side effects, an additional co-analgesic should be commenced. In acute severe neuropathic pain scenarios (e.g. Guillain-Barré syndrome or cancer pain), one may escalate more quickly and have a lower threshold for combination strategies.

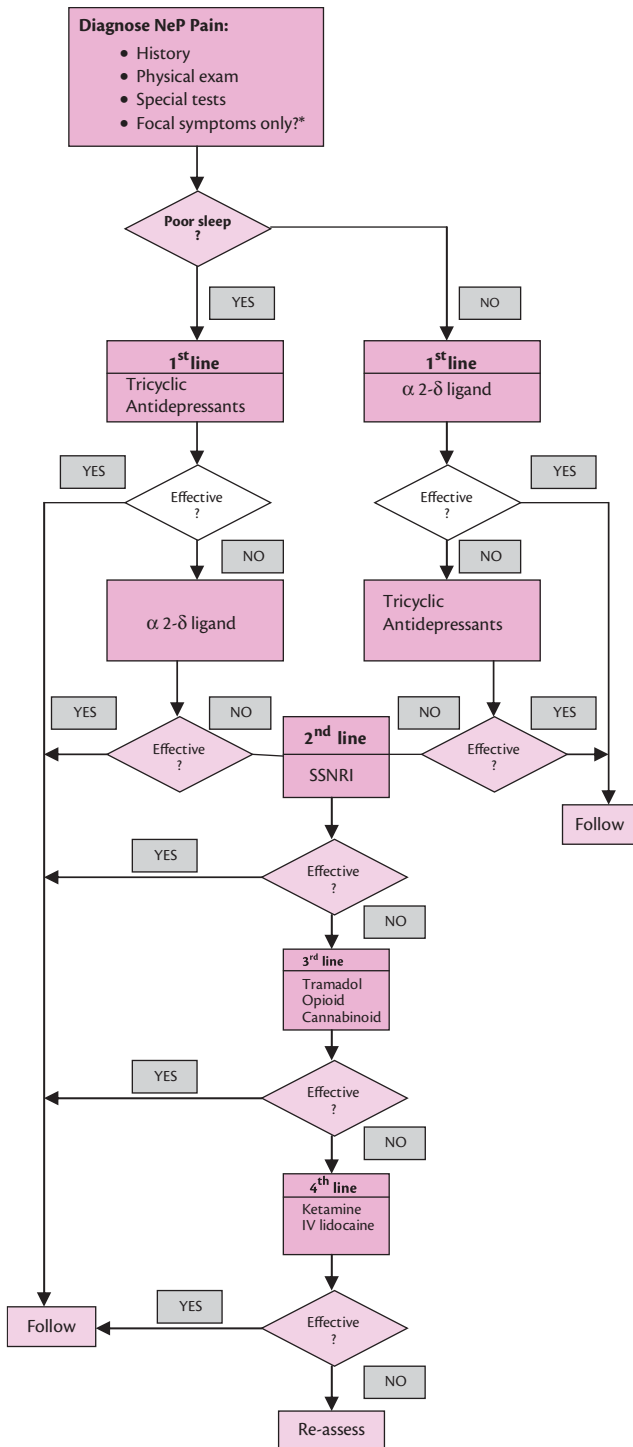

Third-line medications can be added if there is some pre-existing benefit of first or second line, or alone *de novo* if not.

The decision to use fourth-line medications with limited evidence, such as ketamine or IV lidocaine, should only be made at specialist paediatric centres.

### Conclusion

Neuropathic pain in children can be debilitating with significant impact on mood, sleep, and function, whilst posing a difficult challenge to health care practitioners. The challenge is made more problematic with an over reliance on evidence extrapolated from studies in adults, whose neuropathic pain conditions are uncommon in children and may be quite separate phenomena. Clearly, specific screening and diagnostic tools for neuropathic pain in children are required, in addition to good quality multicentre drug trials. In our experience, the early identification and treatment of neuropathic pain in children can often result in effective sustained reversal of symptoms in many cases, likely due in part to the plasticity of the developing nervous system.

Future directions for pharmacological management will include pharmacogenomics, with a view to tailoring specific drug regimens for individual patients, and stem cell research which also carries promise (Braz et al., 2012). However, it must be reiterated that the pharmacological management alone of neuropathic pain is very unlikely to fully alleviate symptoms. Drugs must form part of an interdisciplinary approach incorporating physical, psychological, and occasionally interventional techniques to achieve successful outcomes in children with neuropathic pain.

\*for focal neuropathic pain, topical agents could be used either along with or in lieu of systemic neuropathic medication. In this case 5% lidocaine patch would be the first line followed by capsaicin.

### Case example

A 13-year-old girl diagnosed with Charcot–Marie–Tooth disease (CMT) type 1A (confirmed by genetic testing—*PMP22* gene duplication) was referred to the chronic pain clinic with a 2-month history of neuropathic pain in the hands and feet. CMT disease is a hereditary polyneuropathy condition presenting with distal weakness and muscular atrophy (myopathy). It is a slowly progressing, demyelinating disease of peripheral nerves, and is also known as hereditary motor and sensory neuropathy (HMSN) of which there are several subtypes. Clinical features include loss of reflexes, pes cavus foot deformity, and hammer-toes. It is an increasingly recognized cause of neuropathic pain in children.

The pain was described as a constant burning, tingling and itchy ‘deep’ sensation. There was intermittent stabbing pain in her toes. There were no autonomic symptoms such as changes in colour, sweating, temperature or hair or nail growth, suggestive of CRPS. She rated the pain intensity as 7/10 on the numeric pain scale (NRS) at the clinic appointment. The range of pain intensity scores varied between 6 to 10/10. The average pain score was 7/10. She reported that the pain needed to be 4/10 or less to find it manageable. When asked to score how unpleasant she found her pain she rated it as 8/10. Her sleep was disturbed by pain; taking at least 1 h to fall asleep, and waking her two to three times per night due to allodynia from the bed sheets. She was frustrated rather than depressed; she reported lethargy, reduced energy and difficulty concentrating at school. She was missing 1 day of school per week because of pain. Her physical activities were significantly affected in that she had stopped participating in gym and swimming. There was some evidence of fear-avoidance to her pain behaviours on a background of mild anxiety. Previous pharmacological interventions had not been helpful at either reducing pain or improving function; these included acetaminophen and ibuprofen, and a topical compound of ketamine, ketoprofen, and lidocaine. Neither physical nor psychological interventions had been tried. She lived with her parents and two younger brothers, all of whom were healthy.

Physical examination revealed an age-appropriate, somewhat shy 13-year-old girl in no acute distress (150 cm tall, weight 48 kg). Pain was outlined on the palmar aspect of both hands and feet with reduced sensation. Allodynia and hyperalgesia were present over the toes. Wrist and ankle deep tendon reflexes were reduced. Neuropathic pain secondary to CMT disease affecting the hands and feet was diagnosed; with significant pain related disability. Education was provided regarding the nature of neuropathic pain and a pain management plan comprising pharmacological, physical, and psychological strategies was developed in collaboration with the patient and her parents. She was started on gabapentin 100 mg PO once daily to be slowly increased in a step-wise manner to 300 mg PO three times daily as tolerated.

Physical strategies comprised education around promoting normal function, desensitization, and a graded exercise programme. A psychological evaluation was scheduled to evaluate to what extent cognitive and emotional factors were contributing to pain and pain related disability; with a view to teaching some relaxation and distraction strategies.

The patient was reviewed in the pain clinic 6 weeks later. The gabapentin had been increased to 100 mg PO three times daily resulting in excessive daytime somnolence, with marginal benefit in pain relief. Furthermore, she had difficulty swallowing the pills given their relatively large size. Given that pain was worse at night with subsequent sleep disturbance, she was switched to amitriptyline 10 mg PO every night at bedtime after an ECG was reported as normal. She was advised that the dose could be doubled if well-tolerated and additional analgesia was required. The next time she was seen in clinic, her pain was better controlled, with an average pain intensity score of 1/10 using the NRS. She had stabilized on a 20 mg dose of amitriptyline, which was well tolerated. She also found physical strategies (ice packs, massage) and psychological strategies (distraction, relaxation) helpful. She reported improved sleep, mood (less frustration), and function (participating in school, hobbies, and seeing friends).

## CHAPTER 49

# Sucrose and sweet taste

Denise Harrison, Vanessa C. Z. Anseloni,  
Janet Yamada, and Mariana Bueno

### Summary

Abundant evidence demonstrates pain-reducing effects of sweet solutions in human infants and animals. Analgesic effects persist up to around 1 year of age in human infants, although the effects are more moderate than seen in the neonatal period. Effects are considered to be due to the relationship between sweet taste and the endogenous opiate system. Yet, despite extensive research, knowledge gaps remain relating to the exact mechanisms, the effectiveness and safety of sweet solutions when given over prolonged periods to preterm and sick infants, the effectiveness in sick infants receiving concomitant analgesics, and the effectiveness in children older than 12 months of age. Based on the extensive evidence to support sweet solutions, their use can be recommended prior to commonly performed short lasting minor painful procedures in newborn and young infants.

### Introduction

Calming and pain-reducing effects of sweet-tasting solutions in infants have been demonstrated in more than 150 published studies, and are one of the most extensively studied interventions in infant care (Harrison and Bueno, 2012; Harrison et al., 2010a). With few exceptions, findings of trials, systematic reviews, and meta-analyses have consistently shown that sucrose and glucose reduce behavioural responses during commonly performed painful procedures in diverse populations of preterm and term newborn infants, and infants up to 12 months of age (Table 49.1) (Harrison et al., 2010a, 2010b; Stevens et al., 2010; Tsao et al., 2007). Based on this evidence, sweet solutions are recommended by national and international organizations (American Academy of Pediatrics Committee on Fetus and Newborn et al., 2006; Anand and International Evidence-Based Group for Neonatal Pain, 2001; Harrison and Australian College of Neonatal Nurses, 2006; Henderson-Smart and Australian & New Zealand Neonatal Network, 2007; Royal Australasian College of Physicians, 2005). Yet, despite such compelling evidence and recommendations, use of sucrose or glucose during painful procedures has not been translated into widespread consistent utilization in clinical practice in hospitals (Carbajal et al., 2008; Johnston et al., 2011; Losacco et al., 2011; Stevens et al., 2011) or ambulatory care settings (Harrison et al., 2013; Taddio et al., 2009). Reasons for this

knowledge/evidence practice gap are in all likelihood multifactorial, but may be related to remaining knowledge and research gaps or prevailing myths or controversies concerning analgesic effects of sweet solutions. This chapter will review (1) the mechanisms of sweet taste induced analgesia and (2) the evidence obtained from bench to bedside studies in animals, human infants, toddlers, pre-school children, and school-aged children. Uncertainties, knowledge gaps, and current controversies will be highlighted and translation of knowledge concerning effectiveness of sweet solutions in diverse patient populations and settings will be discussed. Finally, this chapter will provide implications for practice and directions for future research.

### Sweet taste-induced analgesic mechanisms: the animal studies

Analgesic, calming, and distress-reducing effects of sweet taste were first demonstrated in rodent pups in 1987 (Blass et al., 1987). Effects of sweet solutions were demonstrated to occur rapidly, last for several minutes, and were blocked by systemic opioid receptor antagonists.

The effects were reported to be age dependent with a decline in effectiveness as the rodents aged. Analgesic and calming effects of oral sucrose were demonstrated as early as postnatal day 2 to 3, peaked at postnatal day 10, then declined by postnatal day 14, and were ineffective by postnatal day 21; the weaning time of rodents. In the presence of inflammation, the analgesic effects of sucrose (7.5%) are initially present on postnatal day 3 for inflamed forepaw and postnatal day 13 for inflamed hindpaw. By postnatal day 17, the analgesic effects of sucrose were no longer present for both inflamed fore- and hindpaws. These findings support that sucrose is age dependent and also has differential maturational effects that work in parallel to the changes in the endogenous analgesic mechanisms and the developmental features between gustatory and pain pathways in neonatal rats (Anseloni et al., 2002).

Reports from studies of rodents also showed that amongst sweet-tasting solutions there is a rank-order of potency in which sucrose is more analgesic and calming than glucose, and the latter is more effective than fructose and lactose had no analgesic effects (Blass and Shide, 1994). Studies also investigated a possible dose-response function of sugar concentrations; however, increasing the

concentration of sucrose did not result in increased analgesic and calming effects (Blass and Shide, 1994).

### Opioid basis of effects

The neurochemical basis of the sweet-taste analgesia has been investigated both in human and animal newborns. Studies reported that the effects of orally administered sugars and fats are mediated by endogenous opioids (Anseloni et al., 2002; Blass et al., 1987, 1991). Analgesic and calming effects of sweet solutions and milk were reversed by injections of naloxone and naltrexone, non-selective opioid receptor antagonists (Anseloni et al., 2002; Blass and Fitzgerald, 1988; Blass et al., 1987, 1991; Shide and Blass, 1989). Several studies reported the mechanisms underlying sweet-taste analgesia. The stimulation of the taste buds in the oral cavity remains the main mechanistic explanation due to the rapid onset of the effects of sweet solutions given orally. It is clear that oral infusion of sweet solutions do not happen due to somatosensory stimulation in the oral cavity or gustatory stimulation in general,

since distilled water, saline, or other salty solutions do not produce analgesia (Anseloni et al., 2002, 2005; Blass, 1997; Blass et al., 1987; Ren et al., 1997; Shide and Blass, 1989).

Further evidence is needed to describe the mechanisms in which sweet-taste stimulation of the taste buds involve specific nerve branches. One study showed that, in rodents, sweet-taste receptors are located mainly on the palate, which is consistent with reports on the greater involvement of the greater petrosal nerve fibres instead of the chorda tympani fibres (Travers, 1993). The question of the possible contribution of post-ingestional mechanism remains unclear since there has been only one study in human infants and none in animal models. Ramenghi and colleagues (Ramenghi et al., 1999) reported that direct administration of sucrose to the stomach via a nasogastric tube (NGT) had no analgesic effects during heel lance.

Another remarkable finding relating to the basic neurobiology of sucrose analgesia was that oral sucrose did not require involvement of the forebrain, but was dependent on brainstem activity

(Anseloni et al., 2005). Sucrose was seen to activate neurons in the two main brainstem structures involved in descending modulation of pain; the caudal periaqueductal grey matter and the raphe magnus. These findings contribute significantly to the knowledge concerning mechanisms of sweet taste analgesia.

## Sweet taste-induced analgesic mechanisms: the human infant studies

The early animal laboratory studies discussed in the preceding section set the scene for more than 150 studies of sweet taste-induced analgesia in human infants conducted over two decades (Harrison and Bueno, 2012; Harrison et al., 2010a). The first published study identified showing calming effects of sweet solutions in human infants was published in 1989 by Blass and colleagues (Blass et al., 1989), the same authors responsible for many of the early investigations into the stress moderating and analgesic effects of sweet taste in rodents. In this earliest study, 0.2 ml 12% sucrose solution given in two aliquots 2 min apart, to healthy crying, term newborn infants, resulted in immediate calming, immediate cessation of crying, and vigorous mouthing and hand to mouth activity. Sustained calming persisted for up to 5 min. Successive trials continued to demonstrate calming effects of small volumes of oral sucrose on healthy crying infants (Barr et al., 1994, 1999a, 1999b; Blass and Smith, 1992; Graillon et al., 1997; Smith and Blass, 1996; Smith et al., 1992). Such profound calming effects were considered to be non-sedating, with most of the infants remaining alert following sucrose administration (Blass and Ciaramitaro, 1994).

Further research established that calming effects were dependent on sweet *taste* rather than volume. A step-wise sweetness effect on calming was clearly demonstrated, with the sweetest solutions of sucrose and fructose resulting in more rapid and sustained calming compared to the less sweet sugars of glucose and lactose (Blass and Smith, 1992). Lactose was no more effective than water and in fact, led to some infants to cry more. As volumes of 0.2 ml sucrose were equally as effective in soothing infants as larger volumes of 0.6 ml and 1.0 ml, calming effects were considered to be independent of volume (Blass and Smith, 1992).

To further explore the endogenous opioid basis of sweet taste-induced calming, the effects of sucrose on infants with chronic antenatal exposure to opiates were evaluated (Blass and Ciaramitaro, 1994). Sucrose was hypothesized to be ineffective in infants with antenatal methadone exposure and suffering from withdrawal symptoms, due to low circulating endogenous opioid levels precluding an increase in response to sweet taste. Findings were that sucrose was less effective in this population compared to infants with no antenatal methadone exposure, further confirming the association between sweet taste, an intact endogenous opioid system, and analgesia.

Following these studies demonstrating calming effects of sweet taste, the questions turned to whether sweet solutions, if given prior to painful procedures could in fact be analgesic. In the first published placebo controlled trial of sucrose for reducing procedural pain in human newborn infants, Blass and Hoffmeyer demonstrated that 2 ml of a 12% sucrose solution significantly reduced crying duration during capillary sampling via heel lance (HL), compared to water, and 24% sucrose solution combined with non-nutritive sucking (NNS) significantly reduced crying duration during circumcision, compared to water with NNS (Blass and Hoffmeyer, 1991).

These first studies conducted over two decades ago, clearly demonstrating profound and sustained calming and analgesic effects of sweet solutions, set the scene for the conduct and subsequent publication of large numbers of studies, reviews, systematic reviews, commentaries, and guidelines concerning effects of sweet taste in diverse populations of human infants (Harrison et al., 2010a). In the next section, systematic reviews of randomized controlled trials (RCTs) evaluating sweet solutions for reducing procedural pain in the neonatal period will be reviewed.

## Effectiveness of sweet taste in newborn infants

Sucrose has been the most commonly investigated strategy for reduction of procedural pain in infants. As already mentioned, the first study evaluating sucrose during a painful procedure was published in 1991 (Blass and Hoffmeyer, 1991) and was the forerunner for extensive evaluation of sweet solutions for procedural pain management in infants and children over the next two decades. Six years after this first trial, the first systematic review and meta-analysis of studies of sucrose included 13 trials and 982 neonates (Stevens et al., 1997). Procedures investigated were HL (11 studies) and one study each evaluated venepuncture (VP), immunization, and circumcision. Findings were that sucrose reduced cry duration, facial expressions, pain intensity scores, and heart rate compared to water or no intervention, with the exception of one study in which an 18% sucrose solution was used. Fifteen years later, this systematic review has been substantially updated a number of times, with the most recent update in 2013 including 57 studies with 4730 term or preterm infants (Stevens et al., 2013). Predominantly, HL was studied (29) while other painful procedures included VP (nine), eye examination for retinopathy of prematurity (six), combination of procedures (four), circumcision (three), subcutaneous injection (two), NGT insertion (two), bladder catheterization (one), and heel stroke (one). Sucrose consistently and statistically significantly decreased individual behavioural pain indicators, unidimensional, multidimensional and composite pain scores compared to water or no treatment. A meta-analysis including four studies (264 neonates) showed that a range of doses ranging from the pacifier dipped in 24% sucrose up to administering 0.5 ml 24% sucrose significantly reduced Premature Infant Pain Profile (PIPP) scores compared to control or no treatment (1) at 30 sec following HL (weighted mean difference (WMD)  $-1.76$  (95% confidence interval (CI)  $-2.54$  to  $-0.97$ ;  $p < 0.001$ )), and (2) at 60 sec following HL (WMD  $-2.05$  (95% CI  $-3.08$  to  $-1.02$ ;  $p < 0.001$ )). Another meta-analysis including only two trials and 88 neonates showed that sucrose also reduced total crying time following HL. Based on the meta-analyses of four studies, the authors recommended the routine use of sucrose 0.012 to 0.12 g (0.05 ml of 24% sucrose to 0.5 ml of 24% sucrose) be administered approximately 2 min prior to single painful procedures. However, given the broad range of effectiveness of sucrose doses and the heterogeneity of studies in this review, further research is needed to identify a more precise dose for the different gestational ages. The authors also recommended further research in extremely preterm, sick ventilated infants, and relationships between validated pain assessment tools and indicators that measure nociceptive brain activity.

Sweet-tasting solutions other than sucrose have also been investigated. A systematic review and meta-analysis exploring the effects

of solutions other than sucrose included 38 studies, 3785 infants, and eight different procedures (Bueno et al., in press). Glucose was the most frequently investigated solution (35, 92% of trials) with one study each including artificial sweetener, fructose, glycine, honey, and maltitol. Nineteen studies evaluated non-sucrose solutions during HL; ten studies during VP, and three during intramuscular (IM) injections (Table 49.1). Results were analogous to the sucrose systematic review; glucose of sufficient concentrations consistently reduced individual behavioural responses and unidimensional, multidimensional and composite pain scores compared to water or no treatment in preterm and term newborn infants during single episodes of painful procedures. A meta-analysis showed that glucose (20–50%) given prior to HL resulted in a 36 sec reduction in duration of cry (two studies, 90 infants, 95% CI –43.3, –29.5;  $p < 0.001$ ), and a 3.6-point reduction in mean PIPP scores (two studies, 124 infants, 95% CI –4.6, –2.6;  $p < 0.001$ ) compared to water or no treatment.

Both systematic reviews highlighted that analgesic effects were independent of volume of sweet solutions; as small volumes were as effective as larger volumes, yet the effects were reported to be sweet-taste dependent. Sweeter, more concentrated solutions more effectively reduced pain responses compared to less sweet solutions (Bueno et al., in press; Stevens et al., 2013). Although sucrose and glucose consistently reduced behavioural indicators, both reviews reported inconsistent effects of sweet solutions on reducing physiological responses. Inconsistency between behavioural, physiological, and even cortical responses (Norman et al., 2008; Slater et al., 2010) highlights the different mechanisms and actions of sweet solutions as well as the loose correlation in infants between physiological and behavioural responses to pain (Barr, 1998).

The large majority of studies included in the systematic reviews were single episodes of short lasting painful procedures, with fewer studies evaluating sucrose or glucose during procedures of more prolonged duration such as eye examination for retinopathy of prematurity. In addition, very few studies investigated repeated use of sucrose over days, weeks, or months of use. Only three studies to date have examined repeated use of sucrose and showed that sucrose was effective and safe over time (Harrison et al., 2009; Mucignat et al., 2004; Stevens et al., 2005). However, one study of consistent use of sucrose for preterm infants during the first 7 days of life showed that more than ten doses of sucrose in a 24 h period was associated with poorer neurodevelopmental outcomes compared to ten or less doses for infants less than 31 weeks gestational age (Johnston et al., 2002, 2007). In contrast, there were no differences in neurodevelopmental outcomes in preterm infants who received multiple doses of sucrose compared to water over a 4-week period (Stevens et al., 2005). To date, these are the only two studies examining neurodevelopmental outcomes following repeated use of sweet solutions for procedural pain management in infants.

The most important limitation of the systematic reviews was that inconsistencies across studies in outcome measures and metrics used to report results meant that the number of outcomes that could be pooled for meta-analysis was severely restricted. In fact, despite the inclusion of 57 individual studies of sucrose in the 2013 review, the largest number of studies included in any meta-analysis was only four, highlighting the large variability in study outcomes and reporting of statistics. Based on the results of the meta-analyses only, the use of 24% sucrose within a range of 0.05–0.5 ml was recommended prior to single episodes of painful procedures.

However, this recommendation needs to be viewed with caution given the large number of studies demonstrating effectiveness of a broad range of sucrose doses (e.g. 0.02–2.0 ml) that were excluded from these analyses.

In conclusion, systematic reviews and meta-analyses of large numbers of trials show that sucrose and glucose consistently and significantly reduce behavioural responses and unidimensional, multidimensional and composite pain scores in newborn preterm and term infants compared to water or no treatment, during single episodes of commonly performed short lasting painful procedures. Evidence to support use of sucrose or glucose during procedures of longer duration is less clear. As analgesic effects of sucrose persist for around 2 to 5 min in newborn infants (Barr et al., 1994; Blass et al., 1989; Smith et al., 1990), and for a shorter period of around 1 min in 6-week old infants (Barr et al., 1994), administering solutions in divided doses throughout procedures that are prolonged for more than a few minutes may be more effective than single doses. Further research is warranted to confirm this hypothesis. Further knowledge gaps include safety and efficacy of repeated doses of sweet solutions for extremely preterm infants and term infants requiring prolonged hospitalization.

## Effectiveness of sweet taste in infants beyond the newborn period

Does the same sweet taste-induced analgesic effect persist beyond the neonatal period? As highlighted in the first section of this chapter, analgesic effects of sweet taste in rodents declined as the rodents aged. However, this same age-related decline of effectiveness is not as clear cut in human infants. As highlighted in a systematic review and meta-analysis of 14 trials of sweet solutions during immunization in infants aged 1 to 12 months of age (Table 49.1), sweet solutions at sufficient concentrations (at least 30% glucose or 24% sucrose) consistently reduced pain scores and individual behavioural indicators during or following immunization (Harrison et al., 2010b). Effect sizes were however smaller than reported in neonatal studies (Stevens et al., 2013). Conflicting results were also reported concerning: (1) effectiveness of a weak 12% sucrose concentration, and (2) effectiveness of single doses of sucrose for prolonged procedures.

A single dose of 12% sucrose, given 2 min prior to immunization, was no more effective than water in reducing pain in infants beyond the newborn period in two trials (Allen et al., 1996; Poulsen, 2009), yet the same dose was effective in a third study (Dilli et al., 2009). Dilli et al. reported that 12% sucrose not only substantially reduced immunization pain in infants, but also in children up to 4 years of age. These conflicting results may be attributed to possible cultural differences, or maternal interventions, including holding, comforting, and distraction techniques which may have potentiated the sucrose effects (Harrison et al., 2010b). As there are no other published studies of analgesic effects of sucrose in pre-school children during medically related painful procedures, comparison with other findings is not possible at this time.

Whether the analgesic effects of a single dose of sucrose given prior to procedures can be sustained throughout the duration of painful procedures, especially in infants beyond the newborn period, is questionable. Single doses of sucrose given 2 min prior to venepuncture (Curtis et al., 2007) and urethral catheterization (Rogers et al., 2006) were ineffective in reducing pain in infants

beyond the newborn period (Curtis et al., 2007; Rogers et al., 2006). Although neither study reported the duration of the procedures, it is well known that these procedures can take a long time to successfully complete. Single doses of sucrose given 2 min prior to these more prolonged procedures may not result in sustained analgesic effects in older infants. In fact, a key important difference in effectiveness of sweet solutions in infants beyond the neonatal period compared to newborn infants, is the shorter peak effect time and duration of effect, reported to be 1 min only in 6-week-old infants, compared to around 5 min for newborn infants (Barr et al., 1994). This difference has important implications as, based on previous studies showing the peak onset of analgesic effects following sucrose administration is 2 min (Blass and Shah, 1995; Blass et al., 1987); the large majority of study protocols use this timing, regardless of the age of the infants. For infants beyond the newborn period, dividing the dose of sucrose and administering throughout the duration of painful and distressing procedures is recommended to ensure sustained analgesic effects (Harrison et al., 2010b).

## **Effectiveness of sweet taste throughout childhood**

There are few studies of sweet taste for pain reduction in children beyond 1 year of age, and results of these studies are conflicting. Seven published studies investigating sweet taste during painful procedures in toddlers and children aged from 1 to 16 years have been identified (Allen et al., 1996; Dilli et al., 2009; Lewkowski et al., 2003; Mennella et al., 2010; Miller et al., 1994; Pepino and Mennella, 2005). Four trials involved needle-related procedures (Allen et al., 1996; Dilli et al., 2009; Lewkowski et al., 2003) and were included in a recent Cochrane systematic review of sweet-tasting solutions for needle-related pain in children (Table 49.1) (Harrison et al., 2011). Three further trials involved experimental pain invoked by cold pressor testing (CPT) (Mennella et al., 2010; Miller et al., 1994; Pepino and Mennella, 2005).

## **Effectiveness of sweet taste in toddlers and pre-school children**

Only two studies have included toddlers, both of which investigated 12% sucrose during immunization (Allen et al., 1996; Dilli et al., 2009). Both studies included children aged 15 and 18 months of age, but Dilli et al., 2009 also included children up to 4 years of age. Dilli et al. reported that sucrose significantly reduced crying duration and pain scores across all ages of children, while Allen et al. reported a lack of analgesic effects of sucrose compared to water, in infants beyond the newborn period. Possible reasons for the conflicting findings were proposed, including cultural differences and differences in comfort strategies used by parents during the immunization procedure (Harrison et al., 2011). Valid conclusions from these two trials, both of which used 12% sucrose which is considerably less concentrated and less sweet than the 24% recommended for effective pain reduction in newborn infants (Stevens et al., 2013), and both of which included small numbers of children in this age bracket, are unable to be drawn. Children in this age group often become exceedingly distressed during procedures and effective pain management is problematic. Further research determining effective interventions, including use of sucrose, is strongly recommended in this age group.

## **Effectiveness of sweet taste in school-aged children**

Five published studies have evaluated whether sweet taste reduces pain in school-aged children (Lewkowski et al., 2003; Miller et al., 1994; Mennella et al., 2010; Pepino and Mennella, 2005). Lewkowski and colleagues compared sweetened and unsweetened chewing gum during immunization and VP or finger prick (Lewkowski et al., 2003). Results showed no differences in self-report of pain for children who chewed sweet gum either prior to, or during the procedures compared to children chewing non-sweet gum. Three studies were conducted during CPT and results were conflicting (Mennella et al., 2010; Miller et al., 1994; Pepino and Mennella, 2005). Miller et al (1994) reported that pain threshold (time until pain/discomfort was reported) was reduced, but neither pain tolerance (removal of arm from the water), or self-report of pain were effected by 24% sucrose (Miller et al., 1994). Limitations to the study included incomplete data collection with over half the children having no pain tolerance or self-report data. Similar problems with incomplete data collection were also reported in the two other studies of sucrose during CPT in children (Mennella et al., 2010; Pepino and Mennella, 2005). In addition to examining analgesic effects of sucrose, the two more recently published studies also reported that preference for sweet taste influenced whether sucrose exerted analgesic effects. Based on the findings from these five published studies including school aged children, sucrose or other sweet substances are not sufficiently effective as a pain management strategy in this population and their use cannot be recommended.

## **Uncertainties, knowledge gaps, and current controversies**

Despite over 150 studies, predominately including neonates, the use of sweet solutions for painful procedures has not been translated into consistent clinical practice (Carbajal et al., 2008; Harrison et al., 2013; Johnston et al., 2011; Losacco et al., 2011; Stevens et al., 2011). Additionally, there are a number of key knowledge gaps concerning mechanisms of action and effectiveness and safety of sucrose in specific populations of infants. These gaps include:

1. Physiological mechanisms of sucrose.
2. Effectiveness and safety of sucrose given repeatedly over prolonged periods to preterm and sick infants.
3. Effectiveness and utilization of sucrose for managing non-procedural pain and distress in sick infants.
4. Effectiveness of sucrose in sick infants receiving concurrent opioid or equivalent analgesics.
5. Effectiveness of consistent use of sucrose in addition to non-pharmacological pain management interventions in reducing or preventing long-term adverse outcomes of repeated painful procedures in sick hospitalized infants.
6. Effectiveness of sucrose in children older than 12 months of age.

## **Physiological mechanisms of sucrose**

Despite the current understanding of a sweet taste, orally-induced endogenous opioid effect, considered to be due to a beta-endorphin response (Anseloni et al., 2002; Blass et al., 1987; Dum et al., 1983; McKay et al., 1981), the exact mechanism has not been definitively

confirmed in human infants (Taddio et al., 2003). Further research aimed to elucidate the calming and analgesic mechanism of oral sucrose in infants is warranted.

### **Effectiveness and safety of sucrose given repeatedly over prolonged periods to preterm and sick infants**

Only three disparate studies, two trials and one longitudinal study, have evaluated the use of sucrose for prolonged periods (Harrison et al., 2009; Mucignat et al., 2004; Stevens et al., 2005). All three studies showed that sucrose remained effective and safe when used for 4 weeks or longer, however further research is warranted to corroborate these findings.

### **Effectiveness and utilization of sucrose for managing non-procedural pain and distress in sick infants**

This is a key unexplored question which has not been addressed in any published reports to date. Although, anecdotally sucrose is used to calm crying, distressed, agitated hospitalized infants, the effectiveness of sucrose, in this context, as well as the extent of this practice is unknown. As effects of sweet solutions are short lasting, consistent use for ongoing pain and distress could potentially lead to excessive volumes being given over the course of the hospitalization. Setting maximum daily doses may reduce this risk. Tracking the utilization of sweet solutions in hospitalized infants is imperative for furthering our understanding of the degree of sucrose exposure which can in turn, inform if there are any long-term effects based on degree of exposure. Currently there is little evidence to inform the question ‘How much is too much?’. When tracking sucrose use, it is important to be cognizant that sucrose is also present in commonly administered proprietary syrups, including antibiotics, vitamins, and antipyretics (Harrison, 2008).

### **Effectiveness of sucrose in sick infants receiving concurrent opioid or equivalent analgesics**

As the proposed mechanism of oral sweet taste in infants is the invoking of an endogenous opioid response, whether this response can occur in the context of exogenous opioid delivery is an important question. As maintenance doses of continuous opioid analgesics, given for postoperative pain management or for sedation, do not sufficiently reduce pain during acute painful procedures (Carbajal et al., 2005), it is important that the effectiveness of sucrose in this context is evaluated.

### **Effectiveness of consistent use of sucrose in addition to non-pharmacological pain management interventions in reducing or preventing long-term adverse outcomes of repeated painful procedures in sick hospitalized infant**

Adverse long-term effects of repeated painful procedures have been reported. The question whether consistent use of effective pain management strategies including sucrose with NNS and breastfeeding or skin-to-skin care, can ameliorate such effects is not known. The design of such a study is challenging, as a control group would be considered to be unethical, given what is currently known. Furthermore, using historical controls is problematic as rapid changes have been made in many NICU care practices; thus attributing differences in outcomes to pain management practices

could be flawed reasoning. Nevertheless, close follow-up of preterm and sick infants following discharge from hospital, which includes all relevant behavioural and developmental outcomes including pain responses to future procedures such as immunization, and pain sensitivity, will contribute to the knowledge gap regarding long-term effects of effective early pain management.

### **Effectiveness of sucrose in children older than 12 months of age**

Young children often become extremely distressed during medical procedures. Effective management of procedural pain and distress in this age-group is challenging. Whether sucrose can be of benefit beyond 1 year of age is an important question warranting further investigation.

Due to the abundant research consistently showing effectiveness of oral sucrose or glucose in newborns and infants up to 1 year of age during single episodes of short-lasting painful procedures, there is no longer uncertainty regarding benefits of using sweet solutions. It is therefore no longer ethical to conduct further no treatment or placebo-controlled trials of sweet solutions during commonly performed painful procedures in this population (Harrison et al., 2010a). Sweet solutions, with NNS if possible, should be considered a standard of care, along with breastfeeding and skin-to-skin care when feasible. Further research needs to focus on addressing existing knowledge gaps.

## **Clinical practice implications**

### **Practice pointers—guidelines for use**

- ♦ Sweet solutions only work if given orally. Administer in small doses on the top of the tongue, with a pacifier if the infant is able to suck.
- ♦ Solutions need to be sufficiently sweet for endogenous opioid effect (24% sucrose or 25–30% glucose).
- ♦ Suggested doses range from 0.05 to 2 ml in total for single painful procedures.
- ♦ Delivery: only small volumes are required. For newborn infants, a single dose given 2 min before a painful procedure reduces pain during procedures. For infants beyond the newborn period—administer about one-quarter of the dose on the anterior part of the infant’s tongue, one min before the procedure and give remaining dose immediately prior to, and throughout the procedure.
- ♦ For more painful or prolonged procedures, such as eye examination, use additional pain-relieving strategies as recommended.
- ♦ Sucrose or glucose should be considered as adjuvant pain management strategies for procedures associated with moderate to severe pain intensity (e.g. circumcision) and used in conjunction with topical and regional anaesthetics such as dorsal penile block.
- ♦ Document the administration and effectiveness of sucrose.
- ♦ Use additional strategies as feasible such as skin-to-skin care, facilitated tucking, and NNS if part of infant’s care.
- ♦ Support parents to provide pain management and advise of additional ways they can help reduce their baby’s pain (e.g. breastfeeding or skin-to-skin care during non-urgent blood draws,

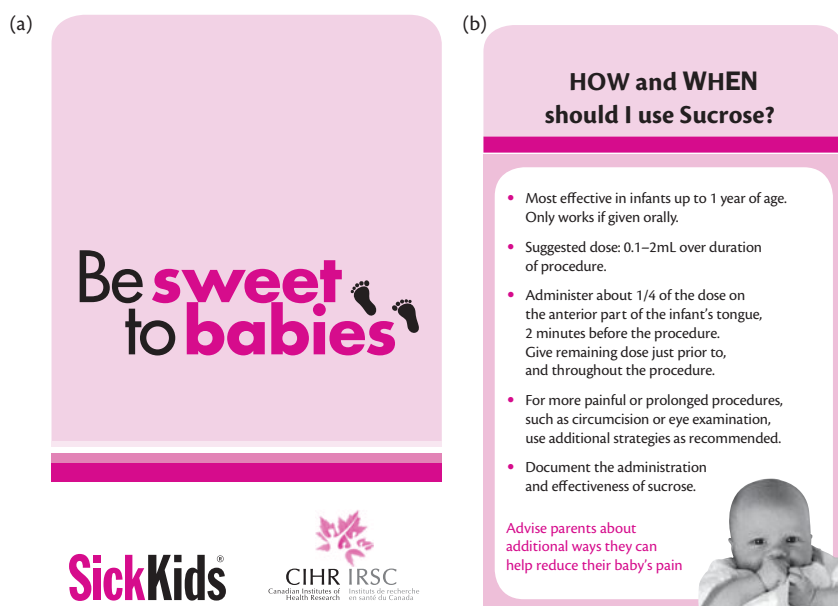

newborn screening, and immunization) (see Johnston and Campbell-Yeo, Chapter 58, this volume on mothercare).

- ◆ Parent education may need to include recommendations to avoid using sucrose for crying in the home.

Availability and accessibility of sweet solutions in all settings where infants undergo painful procedures is necessary to enable their use. Sucrose may be purchased pre-manufactured or made by hospital pharmacy departments or independent pharmacists. Sucrose recipes are available from most large paediatric hospital pharmacy departments. Glucose for intravenous use is readily available in hospitals and can be used orally, as an alternative to sucrose when sucrose is not available. Clearly written, user-friendly clinical practice guidelines which have been approved by relevant stakeholders are necessary to promote consistent best pain

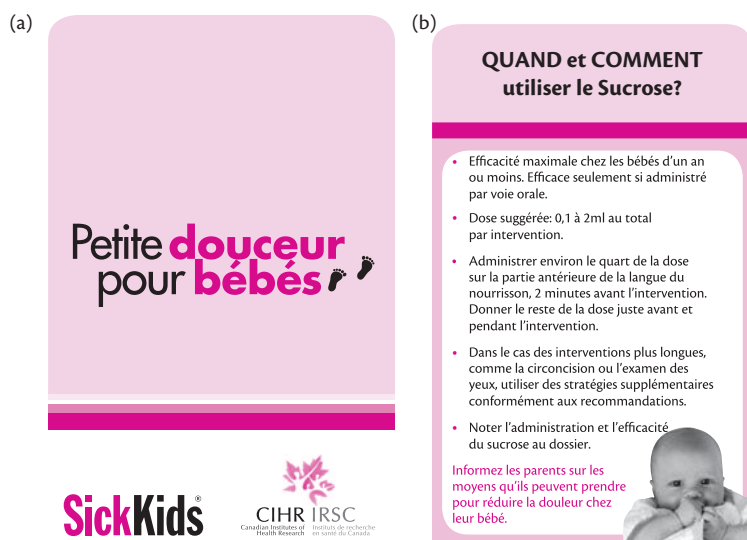

management practices. Guidelines should highlight how to achieve optimal effectiveness of sweet solutions over the course of painful procedures. Examples of mini pocket clinical practice guideline cards developed during the course of a Canadian Institutes of Health Research knowledge synthesis and dissemination project are shown in Figures 49.1 and 49.2.

Infants no longer need to suffer unnecessarily during painful procedures. Sucrose or glucose, alongside other effective pain management strategies including pacifier, breastfeeding, and skin-to-skin care cost little to use, are effective, and can easily be incorporated into infants' care during painful procedures. Health professionals have an ethical responsibility to consistently use best pain management practices and to support parents to do the same. Researchers have an ethical responsibility to work at effectively disseminating their research and to address existing research gaps.

# Psychosocial interventions

*This page intentionally left blank*

## CHAPTER 50

# Cognitive-behavioural interventions

Deirdre E. Logan, Rachael M. Coakley,  
and Brittany N. Barber Garcia

Cognitive-behavioural therapy (CBT) is the most commonly researched and empirically supported psychological treatment for the management of paediatric pain. CBT is a brief, goal-oriented psychotherapy treatment using a hands-on, practical problem-solving approach (Kendall, 2012). It is based on the concept that thoughts, feelings, and behaviours are causally interrelated. This chapter offers an overview of CBT and its application to pain management, describes specific cognitive-behavioural strategies commonly used for paediatric acute and chronic pain problems, presents the empirical evidence supporting these approaches, and highlights key considerations and emerging directions in the use of CBT and related treatments for paediatric pain. Cognitive-behavioural theory

### Cognitive-behavioural theory

Cognitive-behavioural theory, which underlies CBT, represents a convergence of two psychological theories; *cognitive theory* (Beck, 1979), which focuses on mental interpretations of experiences, and *behavioural learning theory* (Thorndike, 1913), which emphasizes the shaping of behaviours through reinforcement. Cognitive-behavioural theory merges these concepts into a model of treatment that targets cognitive appraisals and their influence on emotional and behavioural responses. In practice, CBT relies heavily on the modification of thoughts and behaviours using the principles of reinforcement (Turk and Rudy, 1989; see Slifer et al., Chapter 51, this volume).

### CBT in practice

CBT first emerged in the early 1970s and quickly gained recognition due to both its effectiveness for a wide array of mood and behavioural disturbances and its time-limited model of care. There are many components of CBT that distinguish it from other types of psychotherapy. CBT is usually provided by psychologists, though some skilled licensed social workers and masters-level counsellors also practise CBT. CBT is present-focused and time-limited. It is typically delivered individually in weekly therapy sessions, though it can also be effectively administered in a group format (Barakat et al., 2007; Hayutin et al., 2009; Logan and Simons, 2010). CBT is

highly instructive in nature, often incorporating the use of manuals and workbooks in session, and homework assignments to solidify skills. Within a CBT framework, the therapist and patient work collaboratively to identify problems and design learning experiences that will help to modify negative cognitions and dysfunctional behavioural patterns (Kendall, 2012).

In practice today, CBT is an amalgam of cognitive and behavioural approaches that can be applied in various combinations. Cognitive interventions include the use of skills such as reframing, cognitive distraction, and positive self-talk statements. Behavioural strategies include skills such as relaxation, exposure and desensitization, and modelling. Overarching elements of CBT include education, goal-setting (establishing desired outcomes and incorporating incentives to help achieve these outcomes), self-monitoring (increasing awareness of symptoms and responses through tracking in a diary-like fashion), and problem-solving (identifying obstacles to one's goals and working collaboratively with the therapist to overcome these obstacles). Importantly, a CBT model also attends to the relationship of cognition and behaviour in the context of a child's environment (Kendall, 2012).

### CBT for pain

The use of CBT for pain problems is based on the understanding that pain is a complex biopsychosocial experience shaped not only by underlying pathophysiology but also by individuals' thoughts, feelings, and behaviours (e.g. Keefe and Gil, 1986). Within a CBT framework for paediatric pain, children are taught *cognitive strategies* to identify and restructure illogical or maladaptive thoughts related to pain. Children are also taught *behavioural strategies* to relieve physiological discomfort and relearn adaptive functioning patterns. CBT for pain specifically targets the common distorted thought that pain cannot be controlled (Rogers, 2008). Treatment focuses on modifying this negative belief, enhancing ability to solve pain-related problems, and providing a set of skills for managing pain in an adaptive way. Goals of CBT for pain include gaining a sense of control over pain, reducing fear of pain, enhancing function, increasing feelings of hopefulness and resourcefulness, and improving mood.

Within the literature on paediatric pain, CBT interventions have demonstrated promising improvements in self-efficacy, self-management, family functioning, psychosocial well-being, pain severity, school attendance, and feelings of hopefulness (Barlow and Ellard, 2004). Although the literature has not yet clearly identified which constellation of cognitive or behavioural interventions are most effective for specific groups based on characteristics such as age, gender, or type of pain, there is strong evidence that taken as a whole, these strategies are highly effective for treatment of acute and chronic pain for children as well as adults (Eccleston et al., 2002; Turk et al., 2008).

CBT for pain management typically focuses *initially* on the provision of developmentally targeted education about a child's condition (Rogers, 2008), but *most importantly* on the relationship between thoughts, physiological changes in the body, and behaviours or actions. For example, a child with a chronic pain condition such as complex regional pain syndrome would be taught that she would not cause harm to herself by using her affected limb. A child preparing for a painful procedure would be taught that pain sensations are diminished when attention is allocated away from painful stimuli. Treatment addresses the negative or fearful thoughts (e.g. 'it's going to hurt too much', 'I can't do this') that produce physiological changes (e.g. racing heart, shortness of breath, increased discomfort) and resultant behavioural changes (e.g. poor adherence, withdrawal from activity). CBT also directly addresses maladaptive behavioural responses with the use of strategies such as graded exposure to anxiety producing stimuli and reinforcement for adaptive behaviours.

Specific CBT techniques for paediatric pain

Many cognitive-behavioural techniques are useful both in the acute context of procedural pain (e.g. injections, blood draws, laceration repairs) and for chronic pain conditions (e.g. headache, abdominal pain, disease-related pain, musculoskeletal pain). Each technique reviewed here (see Table 50.1) aims to achieve one or more of the following CBT goals: (1) to direct the child's attention away from pain, (2) to enhance the child's sense of control over pain, and (3) to diminish negative thoughts and feelings related to pain. Although operant strategies (i.e. providing reinforcement or incentives for coping adaptively with pain) are sometimes included within the scope of cognitive-behavioural pain management, those strategies are detailed elsewhere by Slifer et al. (Chapter 51, this volume).

Preparation and psychoeducation

Education is a fundamental component of all CBT interventions. Educational interventions provide a rationale for how and why other cognitive-behavioural strategies can effectively reduce pain and distress.

Preparation for procedural pain

Preparation is a specific educational intervention that entails explaining to the child in advance exactly what the procedure will involve. Typically this includes breaking down the procedure into detailed steps to reduce anxiety and uncertainty. Incorporating sensory information is useful (e.g. 'The nurse will tie a rubber band around your arm; this will feel tight'). Preparation can include showing the child where the procedure will occur and specific equipment that will be used. There are also child-friendly procedure preparation kits available for purchase. It is important to note

Table 50.1 CBT techniques and their typical uses

CBT technique	Used for procedural pain?	Used for chronic pain?
Cognitive reframing	✓	✓
Desensitization	✓	✓
Distraction	✓	✓
Modelling	✓	
Multicomponent packages	✓	✓
Positive self-statements (aka coping statements)	✓	✓
Preparation	✓	
Psychoeducation		✓
Rehearsal	✓	
Relaxation	✓	✓

that detailed preparation prior to a medical procedure may reduce anxiety in some children but may create more anticipatory attention to the procedure than is helpful for others. Both developmental level and individual child coping style may influence utility of these techniques.

Psychoeducation for chronic pain

For chronic pain, psychoeducation entails providing the child and family with a clear explanation of what chronic pain is (e.g. the non-protective nature of chronic pain), how pain signals are transmitted in the body, the role of the brain in processing pain information, and an explanation of the biopsychosocial model of pain (see Pillai Riddell et al., Chapter 9, this volume) and the transactional relationship between stress and pain. Psychoeducation should include a rationale for how and why cognitive-behavioural strategies can effectively reduce pain and restore function. It is helpful to incorporate written educational materials so that children and families can refer back to them as needed.

Evidence base for preparation and psychoeducation

A few randomized controlled trials (RCTs) have examined the effects of preparation on children's response to procedure pain (Harrison, 1991; Tak and van Bon, 2006). A meta-analysis of this evidence shows positive effects of preparation on observer reports of pain during needle procedures but insufficient evidence of effects on self-report of pain or behavioural measures of distress (Uman et al., 2008). Results from one early study (Dahlquist et al., 1985) suggest that individual factors such as the quality (but not quantity) of a child's previous medical experience can affect whether preparation helps the child to cope more adaptively with procedural pain, but more research is needed in this area.

Psychoeducation for paediatric chronic pain is rarely delivered as a stand-alone intervention; thus, there is little literature examining its effectiveness in isolation. One RCT of adult chronic pain patients (Moseley et al., 2004) showed that education about pain neurophysiology resulted in changes in pain cognitions and physical task performance, although the education intervention did not result in changes in reported disability.

## Distraction

The primary goal of distraction is to shift the child's attention away from pain toward more enjoyable, engaging stimuli. Recent theories, backed by empirical support, hold that distraction can exert a powerful analgesic effect that alters the activity on pain processing pathways in the brain (Bantick et al., 2002). Distraction is addressed by Cohen et al. (Chapter 53, this volume). It is briefly discussed here due to its central role in CBT package treatments. Distraction can include both behaviourally oriented strategies such as blowing bubbles or playing a videogame, and cognitively oriented strategies such as non-procedure focused conversation or tasks (e.g. discussing a favourite movie or counting objects). Reading stories or watching videos are also effective distractions for many children. Recently, virtual reality (VR) technology has been employed to create interactive and highly engaging distractions from pain (Lange et al., 2006; Mahrer and Gold, 2009).

### Distraction for procedural pain

Distraction is perhaps the most commonly employed cognitive-behavioural technique for coping with procedural pain. It is easily employed in this setting and can work well across a variety of ages and temperaments. Distraction techniques are generally not time intensive, require little advance preparation, and can be implemented by a variety of clinicians. Parents can also be recruited to employ these strategies.

### Distraction for chronic pain

Distraction works similarly in chronic pain, but the chronicity of the pain requires distractions that remain effective over time. Children and adolescents can identify activities that they enjoy and find absorbing and can be encouraged to use those activities in attempts to cope with pain. Distractions may be social or solitary. School can also be framed as an adaptive distraction from pain, since children are more likely able to distract themselves from pain in school than when home in bed, for example. It is important to work with the individual child to identify the distractions that work best.

### Evidence base for distraction

Among all the specific cognitive behavioural tools for managing procedural pain, distraction has the largest base of empirical support (Cohen et al., 1997; Kleiber and Harper, 1999). Several systematic and critical reviews (Chambers et al., 2009; DeMore and Cohen, 2005; Powers, 1999; Uman et al., 2008) show large effect sizes for distraction as an intervention for paediatric procedural pain, with several recent studies specifically supporting VR-based distraction approaches in comparison to other distraction techniques (Mahrer and Gold, 2009). For further information see Cohen et al. (Chapter 53, this volume).

## Modelling and rehearsal

Modelling and rehearsal techniques are aimed at reducing anticipatory anxiety by helping the child to develop more realistic expectations of a potentially painful situation and increasing comfort and familiarity with the situation. They are therefore most well-suited to the procedural pain context.

### Modelling and rehearsal for procedural pain

For young children who are anxious about anticipated painful procedures, it is often helpful to provide a demonstration (i.e. modelling) of an adult or another child underdoing the procedure and using positive coping strategies. Videotaped demonstrations can be

used for such purposes, or this can be done with a clinician (e.g. child life specialist) or through coaching a parent to demonstrate appropriate coping techniques. Often, children benefit most from education strategies that require them to assume a more active role. Therefore, rehearsal, in which the child him/herself acts out the procedure, such as through medical play, can reduce anxiety and foster positive coping. Often, assuming the role of the doctor or nurse and performing the procedure on a stuffed animal or parent helps children acquire a sense of mastery of an anxiety-provoking situation that may otherwise feel uncontrollable.

In general, studies support preparation and modelling/rehearsal strategies as effective tools for reducing anxiety and distress about medical procedures (Harbeck-Weber and McKee, 1995) with some indication that they may help reduce pain as well. Only one small RCT specifically focused on modelling was reported in a meta-analysis (Zabin, 1982), cited in Uman et al. (2008), and its results were not found to provide sufficient evidence of benefits from this technique alone.

## Cognitive reframing/positive self-statements

Cognitive reframing refers to modifying one's thoughts about a distressing situation so that they are less focused on negative aspects of the situation. Typically, children are taught first to *identify* their negative thoughts or 'self-talk' about pain, then to *challenge* these thoughts, for example, by listing out evidence in support of the thought and evidence against it, and finally to *modify* these thoughts to produce less negative emotional responses. A related technique, positive self-statements, focuses on developing a set of statements that emphasize one's ability to cope positively with a challenging situation. Statements should be brief, such as 'I can do it!' or 'This will be over soon!'

### Cognitive reframing and positive self-statements in procedural pain

A child facing a painful procedure might say, 'I don't want to do this, it will hurt too much!'. Reframing this statement might entail highlighting how quickly the procedure will be over and reminding the child that s/he has strategies for coping with pain, so that the statement can be reframed as, 'This might be uncomfortable, but it will be over soon and I can listen to my favourite song so I don't notice it as much'. Cognitive reframing can take place prior to, during, and after a painful procedure. Using cognitive reframing after a procedure, sometimes referred to as memory alteration, is aimed at reducing the negative memories of a painful experience so they are not as distressing and do not predispose the child toward greater anxiety in subsequent painful procedures (Chen et al., 1999).

### Cognitive reframing and positive self-statements in chronic pain

A child with chronic pain might say, 'This pain is never going to get better'. This negative thinking, referred to as 'catastrophizing', is commonly associated with chronic pain (Sullivan et al., 2001; Turner and Aaron, 2001). The first step in reframing negative or catastrophic thinking is to help a child gain awareness of his/her negative thinking patterns using questionnaire assessments or thought monitoring procedures. Once recurrent negative thoughts are identified, the therapist and child examine evidence supporting the thought (e.g. 'I've seen a lot of doctors but haven't gotten better

yet') and evidence against the thought (e.g. 'there are treatments available that help with this kind of pain'). If the evidence fails to fully support the negative thought, the child is taught to reframe this thought into a new, more adaptive thought such as 'This pain has been with me for a long time, but now I'm working on ways to feel better'. Positive self-statements (e.g. 'I know I can do this!', 'My pain WILL get better') can be used to foster adaptive coping and help challenge negative thought patterns.

### Evidence base for cognitive reframing

There are few published studies of interventions that test cognitive reframing or positive self-statement approaches in isolation; typically they are incorporated into multicomponent CBT packages. One study (Chen et al., 1999) of memory alteration following lumbar puncture found that the group of children who participated in the memory alteration intervention reported less distress and pain than a control group, both immediately after the procedure and at follow-up. However, this small study has not been replicated, so results should be interpreted cautiously. The overall pattern of findings did not meet criteria to be considered efficacious in a meta-analysis (Uman et al., 2008).

## Exposure and psychological desensitization

Exposure and psychological desensitization techniques, widely used in CBT for anxiety problems, involve gradually increasing exposure to a feared stimulus over time while minimizing associated anxiety. The roots of this approach lie in classical conditioning theory, which holds that the association between the stimulus (e.g. needle) and the response (fear, anxiety) is conditioned (learned) and can be progressively weakened. Typically, systematic desensitization entails developing a hierarchy of anxiety-provoking situations ordered from least- to most-feared. Through a process called graded *in vivo* exposure, the child is then exposed to the fearful situations beginning with those identified as least feared and gradually working up the hierarchy. The goal is to encounter the situations safely, without the previously experienced distress, to unlink them from associated anxiety. The clinician may teach the child to engage in positive coping strategies (e.g. relaxation) during this desensitization process.

### Desensitization in procedural pain

Desensitization is a time-intensive strategy that requires a number of sessions with a trained clinician prior to the procedure. Therefore, in the procedural pain context it is typically used with children who are known to have high levels of pain-related anxiety in response to medical procedures such as injections. Prior to a procedure, children can work with a CBT therapist to develop and undergo a systematic process of pairing successive exposures to the feared stimulus (e.g. needle) with relaxation and use of other adaptive coping skills. Over time, the previously feared situation (e.g. the needle stick) ceases to produce significant pain-related anxiety.

### Desensitization in chronic pain

Expectancy effects have a strong influence on pain perception (e.g. Logan and Rose, 2005). Many children with chronic pain develop a pattern of avoiding activities they believe will trigger or increase pain (Martin et al., 2007). Desensitization can be used to reduce this pain-avoidance pattern, unlink the association between activities and fear of pain, and help children to re-engage in activities, which can in turn help to reduce pain.

### Evidence base for exposure/desensitization

A recent systematic review of exposure and desensitization treatments for adults with chronic pain (Bailey et al., 2010) included several RCTs (Leeuw et al., 2008; Woods and Asmundson, 2008) as well as many single case design studies. Current evidence suggests that graded *in vivo* exposure effectively reduces pain and fear-avoidance beliefs and behaviours. Few trials have examined exposure-based treatments in paediatric pain, but this is an emerging area of inquiry given the role of exposure in newer treatment approaches such as acceptance and commitment therapy (ACT). Wicksell and colleagues (2009) conducted a RCT of a ten-session ACT-based treatment with exposure as the primary intervention. The intervention led to greater reductions in pain, disability, pain-related discomfort, and fear of pain compared to standard multidisciplinary treatment (including medication) for children with chronic pain.

## Relaxation techniques: breathing, guided imagery, muscle relaxation

Relaxation strategies focus on acquiring specific skills that can be used to decrease pain perception by promoting a general sense of physical and psychological well-being. This relaxed state is incongruent with intense pain perceptions. Relaxation approaches include deep (diaphragmatic) breathing, progressive muscle relaxation (PMR), and guided imagery techniques. Hypnosis also relies heavily on relaxation. See Liossi et al. (Chapter 54, this volume) for detailed explanations of these specific techniques.

### Relaxation techniques in procedural pain

In the brief context of procedural pain experiences, deep breathing is perhaps the most commonly used relaxation tool. Often props such as bubbles or party blowers are employed, particularly with younger children; these tools incorporate a component of distraction that can augment the benefits of deep breathing. Recorded instructions for progressive muscle relaxation and guided imagery procedures are available and can be used in procedural settings when there is less preparation time available.

### Relaxation techniques for chronic pain

Relaxation is widely used in chronic pain (e.g. Palermo et al., 2010). Learning to employ relaxation strategies in a self-directed manner provides children a greater sense of control over their physiological processes, which may help counteract feelings of helplessness induced by chronic pain. Sometimes these techniques are taught using computer-based biofeedback (see Zeltzer, Chapter 60, this volume), providing concrete visual and/or audio feedback to help the child gain increased awareness over previously involuntary physiological processes. Many therapists provide children with audio-recordings to practise techniques between sessions.

In addition to using guided imagery to develop relaxing images, this technique can also focus on pain-reducing imagery. For example, a child might be guided to imagine the 'pain control centre' in the brain and then locate specific controls that can help to turn down pain messages travelling to a specific body area. These techniques are typically more effective when the child has been guided into a general state of relaxation prior to engaging in imagery exercises (Kuttner, 1991).

### Evidence base for relaxation strategies

Relaxation strategies have a good base of evidence supporting their use with paediatric patients in procedural pain contexts (Dahlquist,

et al., 1985; French et al., 1994). Breathing exercises have been shown to be effective in reducing children's self-reported pain, observer rated distress, and nurse reported distress during routine immunization procedures (Chambers et al., 2009). In a meta-analysis published in 2010, Palermo and colleagues (Palermo et al., 2010) concluded that relaxation as a stand-alone cognitive-behavioural treatment was effective in reducing pain across studies of children and adolescents with a variety of chronic pain conditions including headache, abdominal pain, and fibromyalgia. Typically, however, these strategies along with most others described earlier, are incorporated into multicomponent CBT packages.

## Biofeedback/biofeedback-assisted relaxation training

Biofeedback is a therapeutic procedure that measures and 'feeds back' information about an individual's physiological activity (typically indicators of autonomic arousal) to increase awareness of and voluntary control over those physiological processes (Arena and Blanchard, 1996; Olson and Schwartz, 2003). In the treatment of paediatric pain, biofeedback is often taught in conjunction with other relaxation strategies. As biofeedback is only one component of this approach, it is often referred to as biofeedback-assisted relaxation therapy. Because of the need for trained practitioners (most often psychologists), specialized equipment, and the need for practice to become skilled with these techniques, biofeedback is most commonly used for chronic and recurrent pain conditions.

### Biofeedback for chronic pain

Biofeedback uses electrical sensors to measure and receive information (feedback) about a patient's body. The biofeedback sensors are connected to a computer interface and provide real-time information about physiological processes such as muscle tension. This information provides concrete evidence to patients, demonstrating when they are successful in making positive changes in their body, such as relaxing certain muscles, to achieve pain reduction. Biofeedback for pain management typically incorporates a focus on one or more of the following physiological processes: respiration (pace and depth of breathing), muscle electromyography, peripheral skin temperature, and blood flow or heart rate variability. The 'feedback' can be visual and/or auditory. Visual information can be displayed in graphic or numeric form, such as readout of skin temperature, or it can be transformed into other interactive displays. For example, a child engaging in thermal biofeedback might watch an image of a hot air balloon that gradually rises as the child increases their peripheral skin temperature, or sinks back down if the child's temperature drops. Similarly, relaxing music and images might play as long as the child maintains muscle relaxation below a specified surface electromyograph (EMG) level, but stop if the child surpasses the muscle tension threshold.

Each biofeedback modality has a different mechanism that accounts for its benefits for pain management; for example, EMG biofeedback promotes muscle relaxation, whereas skin-temperature biofeedback produces changes in peripheral and cranial blood flow. These physical changes can be directly beneficial to certain pain conditions, particularly migraine and tension headaches. Biofeedback can also help to foster mind-body connections, decrease overall sympathetic arousal, promote general relaxation, and enhance a child's sense of self control. Children often find

biofeedback engaging and benefit from the concrete, visual aspects of this technique. In fact, studies have shown that children with headaches derive greater benefit from biofeedback compared to adults (Sarafino and Goehring, 2000).

### Evidence base for biofeedback

The most established evidence exists for the use of thermal biofeedback to treat migraine headache and for surface EMG biofeedback in the treatment of tension-type headaches (Herman and Blanchard, 2002). Several studies have demonstrated support for combining biofeedback training with interventions targeting parental responses to pain (Allen and Shriver, 1998; Kroner-Herwig et al., 1998), with results suggesting that this combined approach yields modestly better long-term outcomes than biofeedback treatment alone. In a meta-analytic review, Hermann et al. (1995) found evidence showing greater effectiveness of biofeedback compared to placebo or prophylactic drugs for the treatment of headache.

Studies have also begun to demonstrate the efficacy of biofeedback with paediatric patients with chronic abdominal pain (Schurman et al., 2010; Weidert et al., 2003). Several studies provide support for the use of biofeedback in the treatment of fibromyalgia symptoms (Buckelew et al., 1998; van Santen et al., 2002), although none of these studies is specific to the paediatric population. In their recent meta-analysis of psychological therapies for paediatric chronic pain, Palermo and colleagues (2010) concluded that biofeedback was effective in reducing pain, with an odds ratio of 23.34. However, additional well-designed studies of specific biofeedback modalities and biofeedback assisted relaxation approaches are needed, particularly studies that examine pain conditions other than headache and that include outcomes beyond pain reduction, such as improvements in physical and psychological functioning. Additionally, research is needed to compare biofeedback training to placebo conditions to elucidate its specific and non-specific effects. This is an important design consideration given the potential influence of the novelty of this treatment approach. Patients and families may have a negative bias towards psychological therapy for chronic pain, but may have a positive bias towards expectations for improvement when relaxation or pain management is taught via biofeedback. Teasing apart whether biofeedback-assisted relaxation is more beneficial for chronic pain management as compared to relaxation taught without biofeedback is an ongoing effort in the study of psychological interventions for chronic pain.

## Multicomponent approaches

The techniques described earlier in this chapter are frequently combined into multicomponent cognitive-behavioural treatment packages. Such packages typically combine one or more behaviourally-oriented strategies, such as distraction, breathing, muscle relaxation, modelling/rehearsal, or desensitization, with one or more cognitively-focused strategies, such as imagery/hypnosis, education, cognitive reframing, or positive coping statements (Uman et al., 2008).

### Multicomponent CBT for procedural pain

When using multicomponent CBT in the context of a painful procedure, techniques can be delivered all at once during the procedure itself, or in stages (e.g. with some pre-procedural preparation, some intervention during the procedure, and some post-procedural intervention). Parent or staff coaching in the use of the strategies is

also a common component of these treatment packages in the procedural pain context, particularly for younger children (e.g. under age 8). Although combined approaches may be more time intensive to deliver, which is sometimes a challenge in the procedural setting, children are likely to benefit more from this comprehensive approach.

### **Multicomponent CBT for chronic pain**

For children with chronic pain conditions, psychologists typically teach a broad complement of CBT strategies, often in the context of multidisciplinary treatments that might also incorporate physical therapy and medication use. Patients are encouraged to develop a 'toolbox' of diverse strategies for coping with pain and to adopt a self-management approach to their use outside of therapy sessions. The literature includes many reports of effective multicomponent CBT for treatment of paediatric chronic pain. For example, Sanders and colleagues (1994) developed a comprehensive cognitive-behavioural family intervention for children with recurrent abdominal pain that included psychoeducation, muscle relaxation, breathing, positive self-talk, distraction and imagery techniques along with some operant strategies. Biofeedback and relaxation strategies have frequently been delivered in combination in the treatment of paediatric headache (Holden et al., 1999). Logan and Simons (2010) developed a CBT package consisting of psychoeducation, relaxation, and cognitive reframing skills for children with a range of chronic pain conditions and associated school impairment.

### **Evidence base for multicomponent CBT**

A number of well-validated CBT treatment packages have been created for paediatric procedural pain. Table 50.2 provides examples of empirically tested intervention packages. Many of these packages have been found effective in reducing emotional/behavioural distress both by self-report and observation. Some studies have combined CBT with medications and found the combined approach to improve upon benefits from medication alone (Jay et al., 1991; Kazak et al., 1996). Reviewing empirically supported treatments for procedure-related pain, Powers (1999) concluded that CBT treatment packages were a 'well-established treatment' for procedural pain in children and adolescents. In a Cochrane review, Uman and colleagues (2008) studied psychosocial interventions for 2-to 19-year-olds undergoing needle procedures. They found strong effects on observer reports of pain and behavioural measures of distress for multicomponent CBT interventions. The review by Chambers and colleagues (Chambers, et al., 2009) on interventions to reduce pain during immunization also found combined cognitive-behavioural interventions to be effective for reducing children's self-reported pain and observer-rated distress.

In a series of reviews of cognitive-behavioural treatment for various paediatric chronic pain conditions published in 1999, CBT was found beneficial for children with headaches (Holden et al., 1999), recurrent abdominal pain (Janicke and Finney, 1999), and disease-related pain (Walco et al., 1999). Most evidence was in support of combined treatment packages, although some evidence existed to support relaxation alone and thermal biofeedback alone (Holden et al., 1999; Palermo et al. 2010). In a systematic Cochrane review, Eccleston and colleagues (2009) concluded that cognitive-behavioural treatments were effective in reducing pain in children with headache, with benefits lasting into follow-up assessment points. The authors concluded that these treatments may also benefit

children with other pain conditions including musculoskeletal pain and recurrent abdominal pain, but the number of RCTs for these pain conditions was low.

In a meta-analysis, Palermo and colleagues (Palermo, et al., 2010) addressed some of the limitations of previous reviews by including more recently published trials (focused on headache, abdominal pain, and fibromyalgia) and examining outcomes of functional disability and emotional distress in addition to pain. They analysed 25 RCTs of psychological treatments for paediatric chronic pain, with a total of 1247 participants. The meta-analysis found that multicomponent CBT (along with relaxation therapy and biofeedback training as stand-alone approaches) led to significant reductions in pain, but data were inconclusive regarding effects on functional disability and emotional functioning. Comparing studies on different pain populations, the greatest effects of CBT on reducing functional disability emerged for children with abdominal pain, although it is not clear whether findings related to the type of pain condition or differences among specific interventions. Overall, the evidence in support of CBT for paediatric chronic pain is strong, with the growing body of RCTs demonstrating generally positive effects for a variety of cognitive and behavioural treatment strategies for children with a range of pain conditions. See Table 50.3 for descriptions of sample multicomponent CBT packages for chronic pain.

## **Key considerations in the application of CBT to paediatric pain**

### **Preparing patients for CBT**

It is important for families to have accurate expectations for CBT prior to commencing treatment. For example, it is crucial to dispel the myth that psychological pain management strategies are only effective if there is a psychological cause for the pain. McGrath and colleagues (2003) suggest offering the analogy that morphine is often useful in reducing postoperative pain, but this does not mean that postoperative pain is *caused* by a lack of morphine. CBT is effective for pain management for several reasons. First, children with chronic or acute pain often find direct symptom relief from behavioural pain management strategies. Second, chronic or recurrent pain is often associated with functional impairment (e.g. poor adherence to medical procedures, inability to attend school, activity limitations), and CBT strategies can be effective in improving function even if there is not a reduction in pain. Third, pain and suffering are often linked to feelings of hopelessness, helplessness, frustration, fear, and anxiety. These feelings can exacerbate pain, interfere with medical care, increase disability, and contribute to long-standing mental health difficulties. Thus, CBT has tremendous value for the management of paediatric pain because it has demonstrated effectiveness for: (1) the direct modification of pain sensation, (2) improving maladaptive behavioural responses to pain (e.g. emotional distress, avoidance of activity), and (3) modification of the negative thoughts that can lead to feelings of depression and anxiety (Turk et al., 2008).

It is helpful to explain to children and families that even an empirically effective treatment such as CBT may not eliminate pain immediately or entirely. Over time and with adherence to treatment, however, CBT can often alter a child's experience of pain and thus change their long-term trajectory (Kendall, 2012). After treatment with CBT, it is common for children with chronic pain

**Table 50.2** Sample CBT interventions for paediatric procedural pain

Study	Pain condition(s)	Sample	Study aims	CBT components and Tx dose	Outcomes (pain, function, distress)
Boivin et al. (2008).	Scheduled vaccination	N = 239, healthy 4–12-year-olds	Compare pharmacological + psychological approaches during vaccination to standard medical care (SMC), including pharmacological pain management	Treatment group received: parent + child education, anaesthetic medication, parents providing reassuring statements, and child distraction by blowing bubbles	Compared to SMC, those in the multifactorial treatment group self-reported less pain on a visual analogue scale and facial pain scale. Parents' reports of child's pain were also less for children in the treatment condition vs SMC
Cohen et al. (2002)	Routine immunization	N = 61, 3–6-year-olds	To examine the efficacy of children's use of coping skills training without trained parent/nurse coaches	Treatment included: video instruction in deep breathing; positive self-statements; video modelling; practice	Treatment group did not report using skills during the procedure, perhaps due to lack of parental/nurse coaching. More child training and/or coach involvement might be necessary for effective child coping. Nurses encouraged child coping, whereas parents tended to respond to child distress
Schiff et al. (2001).	Repeated blood draws	N = 43, 4–12-year-olds with HIV	Single group, repeated measures design to evaluate multicomponent pain management intervention for children with HIV under-going repeated venepuncture.	Treatment included: preparation, relaxation, distraction, reinforcement, parent involvement, local anaesthetic cream; no CBT or anaesthetic cream used at baseline	Children reported significant reductions in distress and pain by the second post-intervention procedure and maintained them at the third; parent anxiety was significantly reduced by the second post-intervention procedure
Blount et al. (1992).	Routine immunization	N = 60, healthy 3–7-year-olds	To determine if combined CBT package result in less pain and distress by patient and parent report vs. no-treatment control group	Treatment group received distraction, coping skills training, + use of a party blower for deep breathing; Control group received standard care	Trained parents prompted their child to use the blower more than untrained parents. Trained children engaged in more blower usage than untrained children. Child and parent reported distress lower than both comparison groups

to report that some pain persists, but that the pain is less noticeable and doesn't interfere with everyday life (Rogers, 2008). Children who use CBT strategies to manage procedural pain might report that the procedure was not pain-free, but that it hurt less and they did not feel as anxious or distressed about it.

### Parent involvement

Parents play an integral role in CBT for children with chronic or acute pain, and there are multiple ways to incorporate parents into treatment. Kendall (2012) suggests that parents can be 'consultants, collaborators, or co-clients' in treatment. Parents serve as 'consultants' when they provide information about the social, developmental, or cultural contextual factors that may contribute to their child's pain. This information is crucial for establishing treatment goals and identifying barriers to treatment. Parents are 'collaborators' when they help to oversee the implementation of their child's newly learned cognitive behavioural skills (Kendall, 2012). For example, parents can be taught how to use distraction techniques during their child's painful procedure or taught how to effectively help implement long-term behavioural goals for a child with chronic pain. Lastly, parents can be directly incorporated into CBT treatment with children as 'co-clients' if they are viewed as contributing to the child's presenting problem. For example, many parents become highly focused on their

child's discomfort. This high level of concern may inadvertently reinforce poor adaptation in children with acute or chronic pain presentations. One important CBT goal for parents is to learn to emphasize their child's use of coping skills rather than focusing on the pain itself; decreasing parents' focus on the pain and has been shown to lead to reduced child pain and distress for both procedural and chronic pain (Chambers et al., 2002; McMurtry et al., 2006; Walker et al., 2006). Additionally, research suggests that the association between pain and depression in children is significantly reduced when parents use active pain coping strategies (Williamson et al., 2002).

### Developmental considerations

CBT interventions are most effective when they conceptualize presenting problems within the context of the child's current developmental tasks and milestones. Over the past 10 years there has been a significant increase in research that examines developmental factors as moderators of treatment outcomes, with the goal of improving our understanding of the relationship between the developmental level of a child and specific components of CBT (Holmbeck, 2012).

Because CBT necessitates the acquisition of new or modified behavioural and cognitive skills, attention to a child's development is an important consideration in treatment planning. Although

**Table 50.3** Sample CBT interventions for paediatric chronic pain

Study	Pain conditions	Sample	Study aims	CBT components and Tx dose	Outcomes (pain, function, distress)
Kashikar-Zuck et al. (2012).	Juvenile fibro-myalgia syndrome (FMS)	N = 114, 11–18-year-olds	RCT to compare CBT vs education in reducing functional disability, pain, and symptoms of depression in juvenile FMS	Ten individual sessions in both conditions; CBT included: psychoeducation, muscle relaxation, activity pacing, distraction, problem solving, calming statements, relapse prevention strategies; FM education condition included: education and discussion about FM, pain medications, diet, sleep, exercise, and lifestyle	CBT superior to FM education in reducing functional disability; both groups had decreases in pain and depressive symptoms. Reduction in pain statistically but not clinically significant
Palermo et al. (2009).	Chronic headache, abdominal, or musculoskeletal pain	N = 48, 11–17-year-olds	RCT to compare internet-delivered CBT vs. no treatment on reducing pain intensity and activity limitations	Treatment group vs. waitlist control. Internet treatment consisted of 8 weeks of online modules including relaxation training, cognitive strategies, parent operant techniques, communication strategies, sleep, and activity interventions	Internet treatment group had less activity limitations and pain intensity at post-treatment and 3-month follow-up vs. waitlist group. No differences in parental protectiveness or child depression
Connelly et al. (2006).	Recurrent headaches	N = 37, 7–12-year-olds	RCT to compare CBT via a CD-ROM (+ some therapist contact) vs wait-list control on headache management	Six 1-h CD modules included relaxation, guided imagery, deep breathing, muscle relaxation, coping thoughts, and behaviour management	CD-ROM group had significantly greater improvements in self-reported headache frequency, duration, and intensity vs wait-list controls. Gains maintained at 3-month follow-up
Robins et al. (2005).	Recurrent abdominal pain (RAP)	N = 69, 6–16-year-olds	RCT to compare combination of standard medical care (SMC) + CBT family groups vs SMC alone	Five child–parent CBT sessions included breathing, imagery, relaxation techniques; positive self-talk strategies; minimizing catastrophizing; distraction; parent reframing (i.e. encouraging coping, limiting secondary gains)	Treatment group had significantly less child- and parent-reported pain vs SMC group immediately post-intervention. Group differences maintained at 1 year. Treatment group had significantly fewer school absences vs SMC. No differences in functional disability or somatization

some behavioural strategies such as simple distraction techniques can be effective even among infants undergoing routine immunizations (Cohen et al., 2006), other skills may be less appropriate for younger children (e.g. understanding how changes in thinking impact future experiences). In general, behavioural strategies may be best suited to younger children and more verbal or cognitive strategies may work best for older children. However, given that age is only a proxy for development and that cognitive development impacts the rate and processing of information, executive functioning, meta-cognition, and self-regulation, a thorough understanding of a child's cognitive development is a critical factor in establishing CBT goals and tailoring interventions.

### Relapse prevention

For children with chronic pain or those who undergo repeated painful procedures, CBT interventions should incorporate strategies for relapse prevention. While empirical studies support the

effectiveness of CBT across a wide array of pain-related difficulties, long-term maintenance of treatment gains is less well demonstrated. Symptom relapse is most likely to occur when: (1) pain symptoms change or intensify, (2) a patient's perceived ability to manage the symptoms declines, and (3) there is an increase in psychological distress (Keefe and Van Horn, 1993). Relapse prevention strategies typically include anticipation of minor setbacks, identification of the early signs that distress is increasing, rehearsal of cognitive and behavioural coping skills, and self-reinforcement for adaptive responses to relapse (Keefe and Van Horn, 1993). Additionally, some patients may benefit from intermittent 'tune-ups' with a therapist. This has been conceptualized as the 'dental model' of care (Kazdin, 1997). Meeting every 3 to 6 months after treatment may help to reinforce newly learned skills, identify new onset symptoms before they become problematic, and help children develop more advanced skills to meet their evolving psychological, psychosocial, and environmental demands (Kazdin, 1997).

## Alternative delivery approaches and emerging directions in CBT for paediatric pain

### Group therapy for chronic pain

Group-based CBT interventions have been shown to be cost- and time-efficient and as effective as individual treatment in numerous studies (Morrison, 2001; Sears et al., 2007). The group format also promotes psychosocial support, a particularly salient important factor for children with chronic pain who often feel alienated by their condition. Group therapy programmes can also incorporate other family members in treatment sessions to help modify pain responses within the family environment (e.g. Coakley and Barber 2012; Logan and Simons 2010). In the paediatric literature, group CBT has already demonstrated effectiveness for a variety of pain-related problems such as irritable bowel syndrome (Hayutin et al., 2009), headache (Kroener-Herwig and Denecke, 2002) and pain-related school absenteeism (Logan and Simons, 2010).

### Web-based treatment

There has been a recent emergence of Internet-based CBT interventions for paediatric pain. Internet-delivered CBT for chronic pain has a number of advantages to traditional treatment delivery models. It reduces waiting lists and scheduling conflicts, can be self-paced, and minimizes stigma (Baer et al., 2007; Cuijpers et al., 2008). Both therapist-guided and unguided models exist. Limitations to this delivery method include the automated aspects of this approach, requirement of access to and comfort with appropriate technology, and in the case of unguided approaches, a lack of immediate response to individual needs (Baer et al., 2007; Cuijpers et al., 2008). One meta-analysis (Cuijpers et al., 2008) found that since 2000, six randomized studies have examined interventions delivered over the Internet for paediatric pain. Effect sizes for Internet-delivered CBT for pain were promising (ranging from 0.19 to 0.79), but overall below those found for Internet-delivered CBT for anxiety and depression in children (Cuijpers et al., 2008; Spek et al., 2007). At present, Web-based interventions for pain appear promising but require additional research to determine efficacy (Bender et al., 2011; Cuijpers et al., 2008; Macea et al., 2010).

Palermo and colleagues developed one such programme to deliver Web-based family CBT to adolescents with chronic pain (Long and Palermo, 2009). Adolescents received pain education, relaxation training, and other CBT skills and parents receive training on reinforcement of positive coping, reward systems, communication, and modelling positive coping (Long et al. 2009). Findings of a small RCT found significant reductions in pain and activity limitations post-treatment for the Internet CBT group compared to wait-list control group, with gains maintained at a 3-month follow-up (Palermo et al., 2009). Several Internet-based CBT interventions for children with headaches have also demonstrated reductions in pain and in pain-related negative thinking (Hicks et al., 2006; Trautmann and Kroner-Herwig, 2010).

### Variations on CBT for chronic pain: acceptance and commitment therapy and contextual cognitive behavioural therapy

Acceptance and commitment therapy (ACT) and contextual cognitive-behavioural therapy (CCBT) are relatively new models of psychotherapy commonly referred to as 'third wave' CBT approaches

(Hayes 2004). ACT and CCBT both blend many of the major tenets of CBT with a functional, contextual philosophy of science or rational frame theory (Hayes and Smith, 2005; Hayes et al., 1999). Rather than focusing on controlling or changing unpleasant experiences (e.g. pain), these approaches incorporate acceptance and mindfulness techniques and promote the patient identifying their core values and finding ways to live consistently with these values in spite of pain. These treatments often include exposure-based therapy aimed at increasing psychological flexibility and restoring functioning.

ACT and CCBT for chronic pain management have gained attention in the clinical and research literature given that some individuals with chronic pain need to learn to function in the context of ongoing pain. As opposed to traditional CBT approaches where the goal is to change unwanted phenomena (e.g. reduce or eliminate pain), ACT and CCBT focus on reducing the distressing and disabling influences of pain, pain-related thoughts, and avoidance of potentially painful activities. These approaches assist patients in identifying how to increase functioning and quality of life in accordance with their personal values by shifting away from recurrent struggles with pain (Hayes and Smith, 2005; Hayes et al., 1999; McCracken et al., 2007).

Research on ACT and CCBT demonstrates their effectiveness in adult chronic pain populations (McCracken and Eccleston, 2003; Ruiz, 2010; Vowles and McCracken, 2008). At this time, there is a limited but growing body of literature supporting the application of CCBT and ACT in children with chronic pain (Gauntlett-Gilbert and Eccleston 2007; Wicksell et al. 2009). There is also modest emerging evidence that acceptance and values-based parenting behaviours are associated with improved adolescent functioning in the context of chronic pain (McCracken and Gauntlett-Gilbert, 2011). One RCT comparing CBT to ACT for adult chronic pain found similar outcomes across the two treatments; both approaches led to reductions in pain interference and emotional distress (Wetherell et al., 2011). ACT and CCBT offer promising evidence that the acceptance of pain may be an important component of cognitive-behavioural psychotherapeutic treatment for patients with chronic pain.

#### Case example: The Comfort Ability programme—a brief multicomponent CBT group intervention

Megan is a 14-year-old girl with complex regional pain syndrome in her right lower extremity. Her pain led to significant functional limitations; she struggled to attend school and withdrew from peer and extracurricular activities, spending most of her day at home on the couch. She was referred to physical therapy, but was so fearful of using her foot she was unable to fully engage in treatment. Megan was referred for CBT, but she and her parents were resistant because they felt that Megan did not have a psychological problem. They argued that because her pain was 'real', there would be no benefit in 'just talking about the problem'.

Megan and her parents attended 'The Comfort Ability', a 1-day pain management workshop designed to provide children and parents with a non-stigmatizing, cost-, and time-effective introduction to the principles of CBT (Coakley and Barber, 2012). By addressing the stigma and resource barriers that often prevent families from engaging in psychological services for pain

management, an intervention such as this can provide the three important components of CBT including: (1) psychoeducation to help elicit motivation for pain self-management, (2) cognitive and behavioural skill acquisition, and (3) brief skill rehearsal. Other advantages of a group treatment include the benefit of peer-based psychosocial support.

Within the adolescent group, Megan expressed anxiety about whether her pain would get better, frustration over missed activities, social isolation, school absences, and friction at home. Megan engaged in a goal-setting activity to identify her individual goals for improved functioning, developmentally targeted psychoeducation about how pain functions in the body, interactive discussions and worksheets to learn how to identify and modify negative thoughts and maladaptive behaviours, problem solving skills, and an art activity that promoted self-efficacy. Additionally, she practised behavioural skills such as diaphragmatic breathing, guided imagery, and progressive muscle relaxation. She learned how to use these strategies to manage the discomfort and stress associated with physical therapy and returning to school. Finally, she created a personalized pain management plan, highlighting the individual cognitive and behavioural strategies she thought would work best for her. She left with a manual and a pain management tool kit inclusive of a relaxation CD.

Megan's mother and father attended the parent workshop. They expressed feeling sad, anxious, and overwhelmed by Megan's situation. They shared openly with other parents who had similar experiences. With guidance, Megan's parents were able to identify that Megan's chronic pain was exacerbated by factors such as her transition to a new school, the recent loss of her grandmother, her sensitive temperament, and her perfectionistic personality. They were taught how to minimize their responses to her pain (e.g. refraining from asking her to 'rate' her pain, encouraging her to be functional) and how to support her in using her coping skills. Importantly, they were also provided with guidance for how to advocate for Megan at school so that Megan would be well supported with a school re-entry plan.

Three weeks after attending the workshop Megan's parents reported significant changes in their approach to Megan's care, with observable benefits. They noted that Megan was regularly attending shortened days at school. She was participating in physical therapy and had set a motivating goal of getting her ears pierced when she 'graduated' from her treatment. Her parents noted that she still struggled with 'bad days' but that her mood and function were steadily improving. Megan's parents observed a shift in Megan's thinking and in her approach to pain management. They planned to initiate treatment with a local psychologist to provide ongoing CBT to Megan in order to further her initial gains.

# Operant treatment

Keith J. Slifer, Adrianna Amari and  
Cynthia Maynard Ward

### Introduction

Operant conditioning interventions for clinical pain involve the modification of environmental and social stimuli that are (1) antecedents (discriminative stimuli or setting events) to maladaptive pain behaviour or (2) consequent stimuli that maintain the maladaptive pain behaviour through positive reinforcement (social attention or assistance from others) or negative reinforcement (escape or avoidance of uncomfortable, effortful activity, or of social, academic, or work responsibilities). While aspects of operant conditioning theory have been included in the design of interventions to manage acute paediatric medical procedure-related pain (see Slifer et al., 1995, 2002, 2011), this chapter will not include these studies but will focus on operant conditioning based interventions for illness- and injury-related chronic or recurrent pain.

Before reviewing the history and empirical support for operant conditioning based interventions for pain, in general, and paediatric pain, in particular, it will be useful to note that much of the work in this area has been conducted by psychologists and behaviour analysts who have been trained in the research methods and conventions of the Experimental Analysis of Behaviour and Applied Behaviour Analysis (see Iversen, 2013; Cooper et al., 1987 for more background on these disciplines). These fields employ single-subject experimental designs in which each subject serves as his or her own control and careful, repeated observations are conducted on the same individual across time (referred to as a time series). The individual's behaviour is measured during these observations by recording the occurrence or not of operationally defined behavioural responses, features of the physical and social environment, and sometimes physiological responses of the participant (e.g. blood pressure, heart rate, body temperature, etc.). The preference for single-subject methods and research designs arose from the philosophical perspective that information about what controls behaviour can be learned from studying its variability across environmental conditions within a single participant. Observations of the antecedents and consequences of target behaviour lead to hypotheses about controlling variables. Single-subject research involves systematic control and manipulation of antecedent or consequent variables in order to demonstrate and confirm the hypothesized functional control over the behaviour being studied. The investigator's aim is to show that when hypothesized controlling

variables are manipulated the occurrence of target behaviour can be reliably increased or decreased. In this type of research, rather than obtaining a single or a few observations of a large sample of participants, the investigator obtains many observations of only one or a few participants. One important advantage of this type of research is that variability within subjects is considered important information to be studied rather than error variance to be controlled by averaging across a large group of subjects or by other statistical methods. In single-subject experimental design research an emphasis is placed on replication of demonstrated functional control both within a given subject on different occasions and across settings and replication of the same or similar results for a given intervention across repeated applications with a relatively small series of participants. This is particularly useful when developing and testing new intervention approaches based on cumulative individual subject evidence. This approach is also preferred by behaviour analysts because it allows for more individualization of intervention procedures while basing them on a consistent rationale and set of learning and conditioning principles. This is especially important for working with children whose behaviour patterns are developing based on their ongoing learning experiences. This individualized approach to intervention is a hallmark of Applied Behaviour Analysis, and it is especially useful for demonstrating the effectiveness of novel interventions. These interventions may later become the focus of more conventional randomized clinical trials that assess for generalizability of effects across larger samples of participants. In light of this research philosophy many of the studies discussed in this chapter employed single-subject experimental design and the strength of the evidence derives from replication across studies demonstrating the same or similar behavioural phenomena. This evidence base is supplemented by the few relevant group design studies and systematic reviews across studies that are available in the literature.

### Origins of operant treatment for chronic pain

Although the focus of this book and, therefore, this chapter is on methods for understanding and treating pain in infants, children, and youth, it will be helpful to consider the origins of the operant

conceptualization of pain behaviour in the adult clinical pain management literature. Wilbert Fordyce and colleagues conducted some of the earliest work applying operant behavioural concepts to understanding and treating patients' pain (Fordyce, 1976). He and his colleagues proposed that a significant part of clinical pain is the patient's overt behaviour that can be influenced by myriad social and environmental factors in addition to being influenced by actual tissue damage or irritation (see Fordyce and colleagues' work summarized in Sanders, 2003).

The operant conceptual framework for understanding chronic pain is that consequences that immediately follow pain behaviours may have a powerful influence on the probability of the pain behaviours occurring again in the future. As a result of this behaviour-consequence association, pain behaviours that originated because of body damage or tissue irritation may come under control of consequences and conditioning that occur in the patient's social environment. According to Fordyce, the two general processes that are responsible for this operant conditioning are positive reinforcement and avoidance learning. Positive reinforcement suggests that the occurrence of pain behaviours will increase in frequency if followed by positive consequences. By definition, if a behaviour increases in frequency after a specific consequence consistently follows it, then whatever the consequence was is hypothesized to be a positive reinforcer. Positive reinforcers of pain behaviour may include contingent social attention in the form of attempts to comfort and console, efforts by others to soothe the pain, and providing contingent pain medication (pro re nata, prn, or 'take when needed' medication). Avoidance learning of pain behaviour occurs when the frequency of a behaviour increases after that behaviour allowed the patient to escape or avoid aversive stimulation.

In this process, pain behaviours such as limping, bracing, or activity avoidance become associated with decreased or no pain sensation, and as a result these behaviours are negatively reinforced and are maintained or increase in frequency. In chronic pain patients this process may become elaborated to the point that the anticipation of suffering becomes a conditioned aversive stimulus. Thus, in the context of anticipated pain, if the patient displays protective pain behaviours and pain perception or its exacerbation does not occur, then the same protective behaviours are more likely to be emitted in the future.

Furthermore, Fordyce noted that once such avoidance learning occurs, it requires little ongoing reinforcement to maintain it. In this context reinforcement refers to the avoidance of nociception. If a behaviour occurs due to anticipation of pain and motivation to avoid both the aversive experience of the anticipation (anxiety, physiological arousal) and the nociceptive stimulus, the patient will maintain the avoidance behaviour even if the nociceptive stimulation is never again experienced. In this situation the goal of operant treatment is to prompt and reinforce normative physical activity and arrange the environment such that the patient attempts typical physical activity without the self-protective pain behaviours, and does not experience pain or experiences it at much lower intensity or magnitude.

Fordyce et al. (1968) first applied operant conditioning methods to modify environmental contingencies in order to change chronic pain in an adult patient. These investigators hypothesized that responses by others to overt pain behaviour accompanying the patient's subjective pain experience may reinforce some aspects of the pain behaviour. If this occurs for a protracted period of time,

the environment may come to sustain the pain behaviour even after the condition that caused the pain has resolved. 'Environment' in this context refers primarily to the social environment. That is, overt expressions or demonstrations of pain behaviour may frequently be followed by attention and attempts by family members and/or medical personnel to provide comfort (Fordyce et al., 1968).

The patient in this case had complained of low back pain for 18 years and had decreased ability to function in the physical activities of daily living. She could maintain a maximum of 20 min of continuous activity without reclining to rest. When a pain episode occurred, she ceased all activity, laid down, took pain medication, and cried until the pain subsided. At these times she received a lot of solicitous and ministering attention from her husband and son. She had undergone surgical interventions to remove a herniated disk (the source of nerve root irritation) and a lumbosacral spine fusion to stabilize her spine. After a careful medical evaluation revealed no evidence of remaining neurological disorder, the investigators reasoned that this patient's behaviour was maintained by contingent attention, medication, and rest. Therefore, the first intervention based on operant conditioning theory was to remove the contingent relationships between pain complaints and medication administration. Instead of being provided on an 'as needed' basis in response to pain complaints, the medication was provided according to a standard medication schedule and gradually faded in dosage until completely discontinued. At the same time, the medical and rehabilitation staff were instructed to be as neutral and socially unresponsive as possible to the patient's complaints of pain or discomfort. Instead, whenever the patient was engaged in an out of bed activity and not speaking of her pain the staff provided positive social attention including praise for any observed increase in physical activity. In this way, pain behaviour was placed on operant extinction and physical functioning was differentially positively reinforced. Using these modified contingencies, a programme of occupational and physical therapy was developed that used rest and attention as the positive reinforcer for increasing participation in activities (e.g. weaving) and walking. As a result, the patient showed a marked increase in her activity level and her pain complaints nearly disappeared in a period of about 8 weeks.

During the 1970s and 1980s, a few similar case studies of children were published using the same type of operant behavioural contingencies as those first described by Fordyce and colleagues (1968). For example, Sank and Biglan (1974) used operant procedures within a controlled case study to treat a 10-year-old boy with severe stomach pains. The investigators developed a token economy in which tokens were awarded to positively reinforce non-pain behaviours while attention was withheld from the boy's pain complaints. This treatment was reported to decrease the frequency of pain attacks, the magnitude of the boy's pain ratings, and to increase his school attendance.

Miller and Kratochwill (1979) published another controlled case study in which time out was used to treat a 10-year-old girl with complaints of severe stomach pain that were hypothesized to be maintained by parental attention. The behavioural treatment in this case involved removing adult attention and social activities contingent on pain complaints. With this intervention, pain complaints in the home decreased from two per day during baseline observation to approximately one per week after treatment, and this improvement was maintained at 1-year follow-up. A similar decrease in

pain complaints was reported to occur at school when the same treatment contingencies were introduced.

Varni et al. (1980) also published an early case demonstration that the overt pain behaviour of a child being treated for severe burns could be impacted by modifying environmental contingencies. These authors used a combination of multiple baseline and reversal single-subject experimental designs to document a reduction in the verbal and motor pain behaviour of a 3-year-old child across hospital bedroom, clinic, and physical therapy settings. Behavioural treatment consisted of rearranging reinforcement contingencies to minimize reinforcement of pain behaviour and maximize reinforcement of observed 'well' behaviours; including wearing required splints and participating in exercises in physical therapy.

### **The role of aversive conditioning and escape-avoidance learning in the development and maintenance of chronic pain behaviour**

As already discussed, early operant conceptualizations by Fordyce and colleagues focused primarily on operant extinction of positively reinforced pain behaviour (eliminating pain behaviour-contingent positive reinforcement). However, these investigators subsequently conceptualized some pain behaviour in terms of escape-avoidance learning. For example when pain behaviour occurs in the context of physical exertion, the patient will discontinue the exertion and thereby escape the pain associated with the exertion. With experience, the patient may learn not only to stop physical activity that produces pain or discomfort, but may also learn to avoid the situations in which physical activity might be required. Thus, an adult may begin to avoid going to work, leaving the house or even getting out of bed. Children and adolescents may learn to avoid going to school, participating in athletics, or even having social interactions with peers.

Fordyce et al. (1982) published a description of the escape-avoidance conceptualization along with the case study of a 21-year-old-male with a 15-year history of hospitalizations for 'abnormal abdominal pain'. This publication described a procedural innovation specifically designed to modify chronic pain behaviours that were hypothesized to have been acquired through avoidance learning. In their article, Fordyce and colleagues presented the basic premises underlying the behaviour analysis and treatment of chronic pain, which are paraphrased in the following list (Fordyce et al., 1982):

1. Pain behaviour, defined as indicators of pain and suffering, may become chronic for reasons other than its original aetiology. That is, chronic pain behaviours may have little or no remaining link to nociception from the body site where the pain problem began.
2. A chronic pain problem may persist for reasons other than the originating aetiology, and a parsimonious explanation with empirical support is that chronic pain may be understood in terms of learning and conditioning factors occurring in the interactions between the patient and the social environment.
3. Given that pain behaviours may not be linked directly to nociception in individuals with chronic pain, but instead may be due

to conditioning effects, strategies for treatment can be based on counterconditioning or behaviour-change principles.

4. Multiple behaviour change methods exist that can be focused on modifying pain behaviour directly, rather than attempting to directly change subjective pain perception.

This conceptualization does not suggest that nociception should not be changed directly, if possible, through medication or other medical intervention, but is based on the assumption that in chronic pain cases traditional medical approaches have not been effective in eliminating the patient's pain. In their 1982 case study Fordyce and colleagues demonstrated the effectiveness of behavioural intervention based on this avoidance-conditioning conceptualization. In that case the 21-year-old male with a 15-year history of pain, dizziness, and abnormal gait was treated with behavioural intervention because of his inactivity and severely impaired ability to walk. Treatment was introduced in two phases. First, improved walking was established by reintroducing walking between parallel bars and positively reinforcing patient participation and achievement of increasing distances. In the second phase reinforcement was provided for walking at increasing speeds that were incompatible with the patient's initially abnormal gait. In addition, a therapist met weekly with the patient and on three occasions with the patient's mother. These sessions focused on altering the social consequences of 'sick' and 'well' behaviour displayed by the patient. The therapist practised and taught the mother to withdraw social support for the patient's inactivity and to provide encouragement and social support for his progress with walking. After the provision of this multimodal intervention, the patient became normally active, ambulated normally, and returned to productive activity. After completing treatment he enrolled in and began attending college, and at 21 months post-treatment was maintaining his treatment gains. To demonstrate the effectiveness of this treatment, the authors employed a changing criterion single-subject experimental design. Using this design they showed that each time the criterion for reinforcement was changed, the patient's behaviour changed accordingly to meet the criterion set (e.g. increased walking speed requirement).

### **Application of operant conditioning principles to the management of children's pain behaviour during burn wound care**

Following upon the conceptual and case study publications described earlier, Kelly et al. (1984) conducted a single-subject experimental study using a reversal design with two girls aged 4 and 6 years with severe burns who required daily hydrotherapy, wound debridement, and application of a topical antibiotic medication. In this study, the investigators noted that the child with burns encounters frequent pairings of environmental stimuli (sights, sounds, and smells in the hospital) with pain (nociceptive stimulation from burn wound care). As a result the child likely learns that in the presence of these stimuli he or she experiences pain. The children in this study responded to the pain with crying, thrashing, and other verbal and motor pain behaviours and these behaviours resulted in intermittent escape from or delay of the painful procedures as well as increased attention from adults attempting to soothe the distressed child.

Therefore, the authors employed an operant conceptualization that assumed burn treatment-related pain behaviour is both positively and negatively reinforced over time. They designed their behavioural intervention with this conceptualization in mind. They used a multicomponent behavioural treatment approach to reducing pain behaviour during these painful procedures. The intervention included cartoon viewing as a form of distraction during the procedures and implementation of a star feedback chart. The star feedback chart was used as an incentive for the children to use the TV cartoon viewing for distraction and for crying less than they had during the same procedure on the previous day. Direct observations were conducted and the occurrence of target behaviours was recorded during each 30-sec interval of the procedures. The target behaviours included the child's verbal and motor pain behaviours and parent or physical therapist interactions with the child. Following each treatment session the parent, physical therapist, and child also completed behaviour rating scales of the child's fear, cooperation, and pain using a 9-point scale. The star chart included a colourful graph showing the percentage of intervals during which the child displayed verbal or motor pain behaviour during each medical treatment session.

This intervention that combined distraction and positive reinforcement of decreased pain behaviour resulted in an approximately 40% reduction in the children's pain behaviour. In addition, both children indicated enjoying the TV cartoons (approximately 4 on a 5-point scale, with 5 = 'I enjoyed the TV very much'). Based on the study design and data it was not possible for the authors to determine the relative contribution of the distraction and reinforcement components of the intervention, but they speculated that the star chart positive reinforcement was critical because they had collected preliminary pilot data with three other children receiving the TV distraction only, and these children showed only slight reductions in pain behaviours.

Two caveats about this study should be noted. First, the most painful of these burn procedures are conducted under sedation, but prolonged periods of sedation and sleep are avoided because the child with burns needs to maintain high levels of caloric and fluid intake to prevent dehydration and ensure adequate nutrition for healing. Therefore, the child can benefit from being able to tolerate these treatments with reduced or no sedation as healing progresses. The second caveat stated by the authors is that the goal of this behavioural treatment is not to completely suppress the child's pain behaviour, but to distract the child to decrease pain perception during treatment and to teach the child to control their pain behaviour to some degree (Kelly et al., 1984).

From this pioneering work of Kelly et al. (1984) until the present day, principles of conditioning and learning have been applied to the management of children's pain and distress during burn wound care. A pair of informative review and discussion articles has been published that present a theoretical framework and associated treatment applications for burn wound care in children (Martin-Herz et al., 2000; Thurber et al., 2000). Three psychological principles are presented to help explain the association between burn care, pain and anxiety. The principles include: classical conditioning, operant conditioning, and control coping. Using these principles, the authors describe the developmentally normal emergence of avoidance behaviours that disrupt required wound care for burns. Using case examples, the authors present their conceptualization of how classical conditioning converts neutral environmental stimuli

into anxiety-provoking, aversive stimuli, and nearly simultaneously operant delay, avoidance, and escape behaviours are both intentionally and unintentionally reinforced by medical and family caregivers. These authors also emphasize how the loss of ability to predict and control the environment with respect to aversive stimulation interferes with the ability of children undergoing burn wound care to cope in the hospital environment and likely promotes learned helplessness (Thurber et al., 2000). Following this conceptualization, Thurber and colleagues (2000) point out how behaviours of burn patients that are often labelled as 'manipulative' are, in fact, quite logical from the patient's perspective of trying to learn what will result in reinforcing outcomes or events in the context of burn wound care. Indeed, despite best pharmacological practices complete elimination of pain and distress may be impossible, and escape behaviour shaped through avoidance conditioning is expected and developmentally typical. The authors hypothesize that in the context of burn wound care, pauses and completion of painful procedures are the most salient reinforcers.

Based on this theoretical framework, a number of intervention strategies have been developed and applied. First, one way to reduce the occurrence of repeated undesirable pain behaviours, such as whining, complaining and constantly requesting pain medication, is to give the analgesic medication on a fixed, time-based schedule rather than giving it on an 'as needed' basis in response to increased pain behaviour. Another strategy based on operant conditioning theory that has been recommended is to place excessive pain behaviours 'on extinction' by withholding all unnecessary social attention (consoling, coaxing, apologizing, etc.) while, alternatively, positively reinforcing cooperation and coping behaviours such as participating in safe and distracting activities. Additional treatment strategies are based on the rationale of increasing the child's ability to predict and control at least some important aspects of his or her environment. This can be accomplished by providing the child with a limited quantity of 'passes' or 'break cards' that the child can use to request a brief break from the painful wound care. A case example on the application of this technique to another kind of wound care will be presented at the end of the present chapter. An alternative strategy is to allow the child to take planned or scheduled breaks that are established and explained to the child in advance. Making the temporary termination of painful stimulation contingent on the passing of a preset time interval (using a timer visible to the child) or contingent on the child presenting a break card helps to reduce the development of escape behaviour in the context of burn wound care (Martin-Herz et al., 2000).

Recent research on the use of behaviour analysis in clinical dentistry supports the beneficial effects of providing breaks from uncomfortable dental procedures according to a fixed time schedule. O'Callaghan et al. (2006) demonstrated that when five children (4–7 years of age) were undergoing tooth preparation and restoration procedures, providing them with intermittent, 10 sec breaks regardless of their level of disruptive behaviour resulted in clinically significant reductions in disruptive behaviour. Consequently, the need for physical restraint during treatment was reduced to near zero.

## Pain behaviours as a class of operant responses

Pain behaviours can vary considerably in terms of modality of expression (vocal, verbal, motor), frequency, intensity, and

duration. Yet, as Kalsher et al. (1985) pointed out, a variety of pain behaviours may have a similar effect on the patient's environment (e.g. attention from others, medication administration, avoidance of effortful physical demands). Given their common effect on the environment, these pain behaviours may be conceptualized as an operant response class. Kalsher and colleagues (1985) argued that examination of pain behaviours as a response class may identify behaviours that are most responsive to modification and might facilitate efficient treatment. The treatment efficiency may result from the phenomenon known as response covariation in which a change in the probability of one response in a response class results in corresponding changes in the probability of other members of the same response class. If screaming, crying and facial contortions are all members of the same response class, then an intervention that decreases the occurrence of screaming might also result in decreased crying and grimacing.

Based on this conceptualization, Kalsher et al. (1985) studied behavioural covariation in a patient exhibiting a variety of pain behaviours. These investigators studied the effects of reinforcement and contingent removal of reinforcement on one pain behaviour (screaming) and also measured the effects of these interventions on other pain behaviours that were not targeted directly for treatment. The participant in this study was a 24-year-old male with borderline intelligence and a medical diagnosis of dystonia musculorum deformans, a genetic neuromuscular disorder that is characterized by strong, sustained twisting and writhing motions of the somatic muscles, adduction of the thigh, and continuous torsion spasms with associated severe, chronic muscular pain. A variety of pharmacological treatments had resulted in little improvement and the patient was at risk of residential placement outside of the family home because of the severity of his screaming. In this study, screaming and five other pain behaviours including self-reports of pain were measured while varying behavioural contingencies for screaming. Pain behaviours that were measured in addition to screaming included facial contortions, muscle contractions, help-seeking, and sharp expulsion of breath. The experimental conditions involved non-contingent reinforcement compared to the removal of reinforcement contingent on screaming.

As hypothesized, the pain behaviours did co-vary during behavioural and drug conditions even though the intervention only directly targeted screaming. The untargeted pain behaviours co-varied most during observations that followed rather than preceded pain drug administration. Furthermore, in contrast to the behavioural observation measures, physiological measures (electromyography) did not differ across conditions. Overall, the results of this study demonstrated that pain behaviour such as screaming can be brought under operant control via manipulation of environmental contingencies. Furthermore, because the other pain behaviours co-varied with screaming, together they appeared to form a response class that shared a similar reinforcement history. While this response covariation can be beneficial to the efficiency of behavioural intervention for pain behaviour, the authors caution that behaviour therapy for pain should be conducted in a manner that will assure the maintenance of at least one appropriate but non-disruptive method of pain expression to allow for successful medical management. That is, even though pain behaviours can be manipulated by modifying environmental contingencies, the goal is not to make the patient completely stoic. Having a consistent, reliable measure of pain behaviour is necessary to be able to monitor

the patient's biological status for evidence of illness, tissue damage, or irritation (Kalsher et al., 1985).

## **Systematic reviews of empirical support for the operant conditioning model of pain behaviour; the interactional mixed model of learning and associated intervention strategies**

As can be seen from the case studies and single-subject design experiments discussed earlier, the literature supporting the operant behavioural conceptualization and treatment of chronic pain in children and adults, and of medical procedure-related pain in children, grew steadily during the 1970s and 1980s. Fordyce et al. (1985) published a comprehensive review article on the use of operant conditioning with adult chronic pain patients. These authors reviewed ten studies that supported the efficacy of behavioural interventions to systematically change the behaviour of patients and sustain these changes over follow-up intervals of up to several years. Based on these studies, they concluded that operant behavioural techniques typically applied in the context of interdisciplinary pain programmes have clinically significant effects on overt pain behaviours such as activity level, medication usage for pain, and verbal expression and self-ratings of pain.

Unfortunately, because of the interdisciplinary context in which the interventions were applied, it was not possible to conclude that operant conditioning-based behavioural interventions were solely responsible for the observed changes. Therefore, continued research was encouraged and needed to determine the specific effects of the operant techniques on immediate and long-term pain behaviour changes. Shortly thereafter, Linton (1986b) published a follow-up review that included five additional, somewhat more methodologically sound studies, resulting in similar conclusions that operant based interventions were effective at increasing activity level, reducing medication usage, and to a lesser degree improving subjective pain reports.

Since the pioneering work of Fordyce and colleagues, the operant conditioning conceptualization and strategies based on it have played a predominant role in understanding and treating adult chronic pain patients (Sanders, 1985, 2003). Sanders (2003) discussed, at length, the behavioural conceptualization of pain and the research supporting this model. In this conceptualization clinical pain is defined as 'an interacting cluster of individualized overt, covert and neurophysiological responses capable of being produced by relevant tissue damage or irritation, but also produced and maintained by other antecedent and consequent stimulus conditions'. Sanders' operant conditioning model is based on six decades of behavioural science, which has produced extensive empirical evidence that essentially all voluntary and most emotional behaviours are influenced by their environmental context and consequences. When applied to pain, the operant conditioning model emphasizes the equality of overt gross motor components of pain behaviour with the cognitive/subjective and neurophysiological components. Furthermore, evidence indicates that these three types of pain responses do not always co-vary consistently (are not reliably positively correlated).

Sander's model of pain is based on a larger Interactional Mixed Model of Learning that includes operant and respondent

conditioning and observational learning effects. Fordyce et al. (1982) and Sanders (1985, 2003) argue that most gross motor and many cognitive/subjective responses can be characterized as escape-avoidance behaviours. For example crying, grimacing, avoiding activity and lying down all may allow the individual to remove, escape, or avoid unpleasant stimulation such as painful tissue damage or irritation, or anxiety from anticipation of this aversive stimulation. This, as introduced earlier, is consistent with a negative reinforcement paradigm, in which the termination of an unpleasant or non-preferred stimulus results in an increased probability of the behaviour that brought about its termination. Sanders (2003) elaborates that behaviours strengthened or maintained by negative reinforcement have been shown to be extremely resistant to change without direct intervention to modify their occurrence. This is especially true for avoidance behaviour because the behaviour functions to avoid the aversive consequence. Without direct intervention there is no opportunity for the individual to ever experience the avoided stimulus conditions in the absence of the aversive stimulus (pain perception), and to associate it with other positive consequences. Thus, with behaviour maintained by avoidance learning there is no spontaneous remedial learning mechanism for establishing new responses unless specific alterations are made in the controlling stimulus conditions associated with the avoidance response. Sanders (2003) cites multiple, well-controlled studies demonstrating that pain responses across response categories (cognitive/subjective, gross motor, neurophysiologic) can be influenced significantly by antecedent and consequent stimulus condition changes in both analogue and clinical environments.

Sander's (1985, 2003) conceptual model distinguishes between acute and chronic pain states. In acute pain, neurophysiological and gross motor pain responses are dominant and the most prevalent controlling consequent stimuli are those associated with the reduction of pain perception arising directly from tissue damage or irritation. When pain becomes chronic, pain responses may become more predominantly cognitive and subjective (anticipation, fear and avoidance of pain sensation). In chronic pain conditions, the most prevalent consequent stimuli maintaining pain behaviours involve escape or avoidance of anticipated pain. Indeed, the patient now may be avoiding aversive environmental stressors associated with pain (e.g. physical contact or exertion, social interactions) or confused with subjective pain perception (e.g. symptoms of anxiety, depression perceived as pain). In chronic pain states, this avoidance of physical activity and social interaction is maintained even after the original tissue damage or irritation is greatly diminished or no longer present. In addition, positive consequences such as social attention may play a greater role in chronic pain.

Given that the antecedent and consequent stimuli that maintain pain behaviour may have shifted when pain has become chronic, it is necessary to consider, and when possible, to modify these maintaining variables. As indicated by Sanders (2003), the effectiveness of any pain intervention is a function of the extent to which it significantly alters the primary antecedent and consequent stimuli initiating and maintaining the pain responses. For example, if a patient is actually experiencing tissue damage or irritation (an antecedent condition) then interventions that do not change the perception of this stimulus will not be effective. Rather, escape-avoidance motivated pain behaviour (e.g. avoiding physical activity) will be maintained to the extent that the behaviour reduces or eliminates perception of pain resulting directly from the tissue

damage or irritation. Interventions that may reduce pain perception include medication, nerve blocks, cognitive-behavioural coping strategies (distraction, hypnosis, controlled deep breathing, progressive muscle relaxation, visual imagery), acceptance and commitment interventions, and other physical interventions (heat, cold, massage, acupuncture, electrodermal stimulation). In situations in which environmental and psychosocial stressors are the antecedent events that set the occasion for pain behaviours, and these behaviours are positively reinforced by special social attention or ministering behaviour from others, and/or are negatively reinforced by physical, social, educational or work activity avoidance, these maintaining variables must be addressed or pain treatment will not be effective.

Following the logic and model just presented, Flor et al. (2002) conducted a study of the role of operant conditioning in the development and maintenance of chronic pain. The study compared 30 adult patients with chronic back pain to 30 healthy matched control participants on their verbal and neurophysiological responding to an operant conditioning paradigm. The results showed that both groups' verbal reports were able to be conditioned, but the patients with chronic low back pain showed different cortical and electromyographic responses. Specifically, the patients with chronic pain were more easily affected by operant conditioning factors at both the verbal and neurophysiological level. Flor and colleagues hypothesized that individuals with greater susceptibility to conditioning effects may be more likely to develop chronic pain conditions. In support of this hypothesis, there is recent evidence that after experiencing painful stimulation in an experiment, chronic pain patients evidenced decreased diffuse noxious inhibitory control (DNIC) in the brain when exposed to subsequent painful stimulation, while healthy control participants (Meeus et al., 2008) and individuals with major depressive disorder did not show this diminution of DNIC (Normand et al., 2011).

### **Positive reinforcement of wellness behaviour and the combination of operant and cognitive-behavioural interventions for clinical pain**

It is important to note that operant interventions for pain also include modification of antecedent and consequent stimuli in order to strengthen wellness-oriented behaviours that are alternatives to, or incompatible with, maladaptive pain behaviour. Examples of positive alternative behaviours include participation in therapy, use of pain coping strategies (distraction, muscle relaxation, positive self-statements), increased physical and social activity, reduced use of narcotic pain medications, and return to role functioning (i.e. school or work).

In his excellent review article on operant therapy with patients with chronic pain, Sanders (2003) discussed the evidence base supporting the effectiveness of these operant interventions, and emphasized that although operant conditioning can play a major role in modifying pain behaviour, it is not considered a complete or comprehensive treatment for clinical pain. That is, medical, physical and cognitive-behavioural interventions also should be used, when appropriate, in addition to operant behavioural treatment strategies. In clinical practice, operant procedures are rarely, if ever, used in isolation, and research evidence supports the benefits of

combining these strategies with cognitive-behavioural techniques such as distraction, relaxation training and cognitive coping skills training. The evidence indicates that the addition of cognitive-behavioural techniques to operant conditioning may significantly enhance the treatment effects accomplished with operant conditioning alone (Compas et al., 1998; Keefe et al., 1992; Lindstrom et al., 1992; Moraley et al., 1999; Sanders, 2003; Van Tulder et al., 2000). Based on his literature review and similar previous reviews by others, Sanders (2003) concluded that there is strong and substantial evidence for the effectiveness of operant conditioning interventions demonstrated primarily with adult patients with low back pain. The evidence supports that operant conditioning alone or in combination with other treatment (e.g. cognitive-behavioural) strategies can produce significant and sustained improvements in general activity level, work behaviour, use of pain medication, and to a lesser degree subjective pain intensity ratings of patients with chronic pain when applied in either inpatient or outpatient settings. The evidence base is strong for adults with low back pain, but there are fewer methodologically rigorous data on the efficacy of operant conditioning-based interventions on other pain conditions such as complex regional pain syndrome (CRPS), fibromyalgia, and headache. The research evidence on operant conditioning intervention effects with children, adolescents, and geriatric populations with diagnoses other than low back pain (either acute or chronic) were found to be less well developed when Sanders conducted his 2003 review.

## Empirically supported psychological treatments for recurrent abdominal pain

Functional abdominal pain is one of the more frequently researched types of chronic pain. In these studies a number of factors associated with the exacerbation and regulation of pain behaviour have been identified (e.g. regulation of afferent input by the CNS, the patient's capacity for sustained attention to bodily sensations and painful stimuli, the amount of caregiver attention paid to pain behaviour, the child's emotional responding to pain, and the amount of effort devoted to using active coping strategies) (Hyams and Hyman, 1998; Lipani and Walker, 2006; Zeltzer et al., 1997, 2006).

With respect to operant behavioural conceptualizations of chronic functional pain in children, operant principles have been hypothesized to be a possible factor in the development of recurrent abdominal pain (RAP). The specific reasoning is that caregivers or others in the child's social environment may inadvertently reinforce illness behaviour and maladaptive coping strategies in the child. Children may receive increased parental attention and experience other reinforcing consequences for their pain complaints (e.g. being excused from school or household chores, or being allowed to avoid stressful social situations with peers; Janicke and Finney, 1999).

Other investigators have adopted a social learning (aka. observational learning or modelling) theory to explain the development of RAP (see Oster, 1972; Robinson et al., 1990; Stone and Barbero, 1970; Walker et al., 1991, 1993, 1994, 1995; Walker & Zeman, 1992; as cited in Janicke and Finney, 1999). According to social learning theory the child observes the pain complaints and corresponding reinforcement contingencies experienced by another person in his or her environment (usually a close family member) and adopts the same behaviour to deal with personal stressors. In support of

this theory are studies indicating a significant relationship between a family history of chronic pain and the occurrence of RAP. This relationship may be due to greater emphasis on bodily sensations throughout the family or modelling of illness behaviour by family members.

A few intervention studies based on operant and social learning theories have been conducted, and this literature was reviewed by Janicke and Finney (1999) to search for empirical support for treatments for RAP. Janicke and Finney (1999) found that based on the available studies and their methodological quality, operant procedures alone did not meet even the more lenient criteria for a 'promising' intervention. Dietary fibre treatments for RAP associated with constipation meet the criteria for a 'promising' intervention, and cognitive-behavioural interventions for RAP meet the criteria for a 'probably efficacious' intervention. While the two case studies using operant treatment alone reviewed by Janicke and Finney (1999) did not meet even the least stringent criteria for empirically supported 'promising' interventions, these early preliminary studies demonstrated preliminary evidence that operant conditioning principles have some influence on the symptoms that are reported by children with RAP, and they set the stage for pursuing alternatives to medical treatment for RAP, including cognitive-behavioural interventions that utilize operant procedures as part of their treatment strategies. From the time of Janicke and Finney's (1999) review to the present day, operant interventions alone rarely have been recommended for RAP or other chronic pain conditions, but have been frequently combined with cognitive-behavioural techniques (Banez and Gallagher, 2006; Blanchard and Scharf, 2002; Finney et al., 1989; Humphreys and Gevirtz, 2000; Linton, 1986a, 1986b; Sanders et al., 1989, 1994; Vervoort et al., 2011).

Robins et al. (2005) conducted a randomized controlled trial of a cognitive-behavioural family intervention for paediatric RAP. The intervention employed a social learning theory conceptualization of RAP, emphasizing the interactive effects of skill deficits in the child and maintenance of symptoms within the context of family interactions. Intervention strategies included presenting this conceptual model to both child and parents, instructing children on active pain management techniques (deep breathing, imagery, relaxation, positive self-statements) using modelling and behavioural rehearsal, and teaching parents more appropriate ways to respond to their child's pain behaviour (reinforcement of behaviour incompatible with pain behaviour, minimizing discussion of pain, refraining from allowing the child to gain special privileges or avoid age-appropriate responsibilities due to pain behaviour). Children and parents receiving the cognitive-behavioural intervention reported less abdominal pain and fewer school absences (Robins et al., 2005).

Hicks et al. (2006) conducted an intervention study with 47 children and youth (ages 9–16 years) with recurrent headache or abdominal pain. The 47 participating youth were randomly assigned to an Internet-based intervention group ( $n = 25$ ) or a standard medical care waitlist control group ( $n = 22$ ). The main components of the cognitive-behavioural intervention were relaxation skills training (deep breathing, visualization/imagery) and cognitive strategies (self-talk). Clinically significant improvement was defined a priori as a 50% or greater reduction in pain diary scores. Using this definition, 71% of the treatment group improved compared to 19% of the control group at 1-month follow-up, and 72% compared to 14% improved at 3-month follow-up.

## Parent–child interactions

As can be discerned from the various operant and cognitive-behavioural and social learning-based studies described earlier, conducting parent training to change the ways in which parents respond to their children's pain versus wellness and coping behaviour is a common component of many of these intervention studies. The associated hypotheses are that parents or caregivers of children with chronic pain place too few demands on their children, attend excessively to pain symptoms, allow their children to escape or avoid activities and responsibilities because of pain behaviour, and allow their children to assume a developmentally inappropriate level of dependence on the parent or caregiver. They may try to protect the child from symptoms by decreasing activities and demands. They may increase the child's distress by overt expression of their own distress, and poor regulation of their own anxiety and frustration (Garber et al., 1990; Liakopoulou-Kairis et al., 2002).

In support of this conceptualization, Walker et al. (1995) studied parents' reactions to somatic complaints associated with unexplained illness and documented that parents often modify their interactions with their children in the presence of pain complaints or illness behaviour. Other studies by Walker and colleagues have reported similar findings that parents tend to encourage children to adopt the sick role for gastrointestinal symptoms (Walker and Zeman, 1992), and children with RAP often have families in which there is greater parental attention to abdominal pain (Walker et al., 1993). Furthermore, a laboratory study by Walker and colleagues (2006), experimentally induced visceral discomfort as an analogue of abdominal pain, and demonstrated that when social attention is provided contingent on gastrointestinal symptom complaints, these complaints nearly doubled in both children with a history of abdominal pain and controls without a history of abdominal pain.

Parents also may model pain behaviour (Schanberg et al., 2001). Parents' expressions of sympathy, attention to symptoms, emotional reactions, modelling of symptoms, and reinforcement of pain behaviour by allowing escape/avoidance of responsibilities, all have been associated with greater pain and disability in their children (Fordyce, 1976; Payne and Norfleet, 1986; Philips, 1987). A number of studies support that in at least some families, the child's pain symptoms play a functional role within family interaction patterns and relationships. In these families, functional disability may be more a function of these interaction patterns than of the subjective experience of pain (Covelman et al., 1990; Kopp et al., 1995; Logan and Scharff, 2005; Naidoo and Pillay, 1994; Palermo, 2000; Scharff et al., 2005). Other studies have examined the social consequences of chronic pain in children (Van Slyke and Walker, 2006; Walker and Zeman, 1992; Walker et al., 1993, 2002). Parental responses studied have included minimizing (shifting focus away from pain behaviours, or reacting in a negative or punishing manner), solicitous responses (encouragement, reinforcement, frequent attending to pain), and protecting (excusing child from regular activities, allowing child to miss school and to stay in bed, etc.) (Van Slyke and Walker, 2006; Walker et al., 1993). More solicitous parental responses have been associated with greater sick role behaviour and greater functional disability independent of stress level or pain intensity (Gidron et al., 1995; Walker et al., 2002; Whitehead et al., 1994).

Peterson and Palermo (2004) studied 215 children between 8 and 16 years of age with chronic or recurrent pain conditions (headache,

juvenile idiopathic arthritis, sickle cell disease) and their parents in order to examine how children's distress, parent indulgence and child functional disability are interrelated. Hierarchical linear regression analyses indicated that solicitous parental responding to child pain behaviour significantly predicted functional disability after controlling statistically for pain intensity. Furthermore, for children with greater distress (depression or anxiety symptoms), parental solicitous responses to the child's pain reports were more strongly associated with increased functional disability than for children with fewer symptoms of anxiety or depression (Peterson and Palermo, 2004).

## The interdisciplinary behavioural rehabilitation model for treating chronic paediatric pain

Some clinicians and investigators have advocated using an interdisciplinary rehabilitation approach to the treatment of pain-associated disability syndrome (PADS) in children and adolescents (Bursch et al., 1998, 2003; Hyman et al., 2002). PADS is characterized by severe disability that continues for 2 months or greater (Bursch et al., 2003). PADS describes a chronic pain condition with frequent and severe difficulties in functioning, regardless of the location or cause of the pain (Bursch et al., 1998; Zeltzer et al., 1997). In PADS the actual tissue damage sustained by the patient, the perceived severity of the condition, and the degree of disability exhibited are often widely discrepant. PADS occurs with many variations in the aetiology and source of the original pain. It may begin with illness, injury, viral infection, or developmental or psychological challenge. In many cases the original trigger may not be identified. There also is wide variation in the time course of the development of the disability. Bursch and colleagues hypothesized that PADS develops when a physical trauma, illness, or other life circumstance becomes overwhelming to a vulnerable child who has poor coping skills and cannot regulate his/her own distress. The physical symptoms may allow the child to avoid or escape the stressor, associated discomfort, and negative emotions. Consequently, the child may fail to develop positive coping strategies and a behaviour pattern in which avoidance of stressful or painful stimulation occurs along with increasing dependence on others, social withdrawal, avoidance of school and physical activity, and progression of functional disability.

In the interdisciplinary behavioural rehabilitation model, children and families are encouraged to accept pain as a symptom that may or may not go away. They are encouraged to move their focus away from total elimination of pain as their sole objective. When underlying pain mechanisms can be identified, they are treated medically to the extent possible. However, central emphasis is placed on reinforcing more independent child functioning in activities of daily living, academics, social and physical activities. Interdisciplinary rehabilitation therapies are provided to treat specific symptoms of anxiety, depression, avoidance behaviour, diminished muscle strength, limited range of motion, and academic deficits, and to teach active coping skills to the child and family. Finally, adaptive functioning instead of pain severity is used to measure progress.

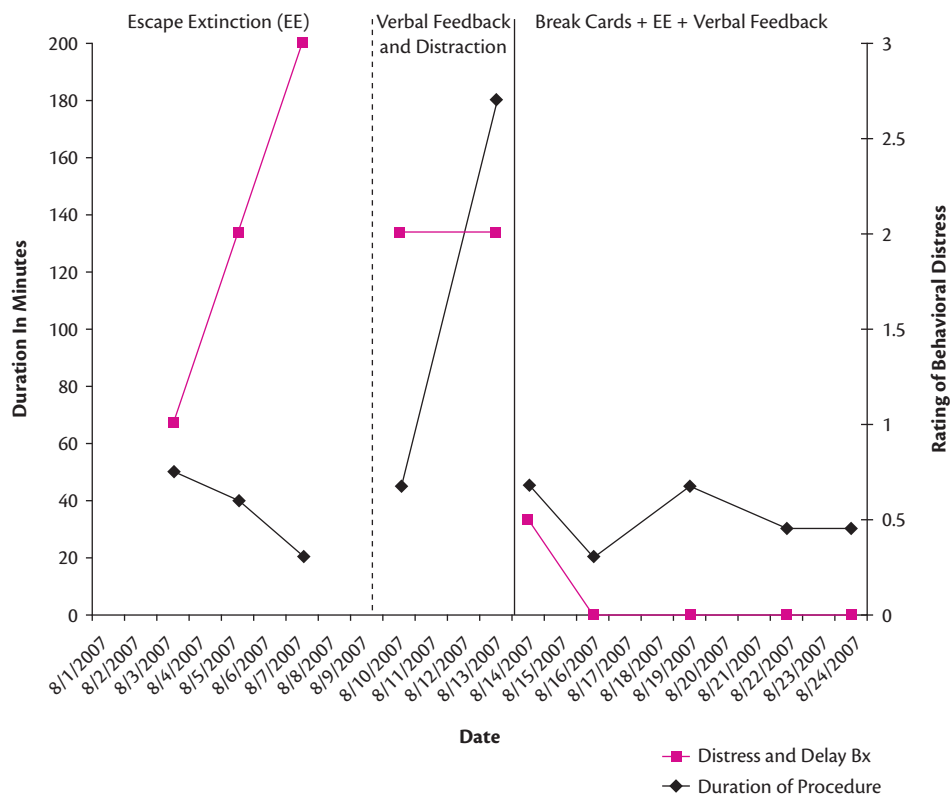

An inpatient interdisciplinary rehabilitation setting may be ideal for implementing systematic behavioural interventions to shape functional behaviour and reinforce its generalization across settings

and situations (Amari et al., 1998; Palermo and Scher, 2001). However, there are few published data on inpatient interdisciplinary rehabilitation programmes that employ behavioural and cognitive-behavioural interventions in a comprehensive and systematic manner to treat chronic pain associated disability. In one case example, Palermo and Scher (2001) described improvements in the physical and psychosocial functioning of an adolescent with a severe pain disorder following an inpatient rehabilitation admission. Eccleston et al. (2003) studied the effects of a 3-week interdisciplinary residential programme that emphasized cognitive-behavioural and physical therapy interventions on 57 adolescents with chronic pain and their caregivers. Their results showed that the intervention effectively decreased distress and improved overall functioning and school attendance. Hechler et al. (2009) studied the effectiveness of a 3-week multimodal inpatient pain treatment for 167 adolescents with various pain disorders. Patients were evaluated at baseline and 3 months post-treatment. Results suggest that 72% and 45% of the patients demonstrated clinically significant changes in pain-related disability and pain intensity respectively.

More recently Maynard et al. (2010) conducted a study to assess the outcome of an inpatient interdisciplinary behavioural rehabilitation protocol to treat children and adolescents with pain-associated disability and distress. The conceptualization and the intervention approach were based on the prior work of Zeltzer et al. (2006). Maynard et al. (2010) conducted a retrospective review of the clinical outcomes from a sample of children and adolescents admitted to an inpatient rehabilitation programme for treatment of

PADS. The investigators hypothesized that the group would exhibit significant improvement across measures of functioning after completing the inpatient intervention protocol as compared to their pre-admission functioning. As a group, the participating patients showed clinically and statistically significant improvements in daily functioning and physical mobility after receiving the interdisciplinary behavioural rehabilitation intervention. Clinical significance was determined by comparing patient's admission and discharge functioning and physical mobility scores. Upon admission patients typically had significant difficulties with self-care, cognition and mobility. At discharge, the patients functioned more autonomously. The patients also showed improvement in school participation, sleep, and medication use. The patients were responsive to differential positive reinforcement of coping behaviour and compliance with task demands of gradually increasing difficulty within the rehabilitation context.

For those with available follow-up information, physical functioning was maintained or continued to improve after discharge. The investigators speculated that the protocol was feasible across development because of individualized shaping procedures and cognitive-behavioural interventions that could be modified for different ages. The use of shaping allowed the children to experience their first successes in small steps, which may have helped to promote coping, motivation and perception of self-efficacy. The rehabilitation hospital setting provided an environment in which multiple staff members prompted and differentially reinforced functional gains and coping behaviour while not reinforcing pain or illness behaviour. This

**Figure 51.1** Observer ratings of Mark's distress and delay behaviour (squares) and the duration of the procedure in minutes (diamonds) across escape extinction, verbal feedback and distraction, and verbal feedback + distraction + escape extinction + break cards conditions.

Reproduced with permission of the author from Kim, F., Slifer, K., Amari, A., Herman, L., and DeMore, M., *The Utility of Operant Choice Using Patient-Controlled Break Cards during an Invasive Medical Procedure*, May, 2009 which was previously presented as a poster at the Annual Convention of the Association for Behavior Analysis International, Phoenix, AZ.

approach involving both fading of activity demands and shaping of increased effort and duration of physical functioning is consistent with the results of a randomized prospective clinical trial conducted with adults with low back pain, which combined graded activity goals and operant conditioning to significantly increase the patients' probability of returning to work and reducing their long-term use of sick leave (Lindstrom et al., 1992).

The emphasis on functional measures rather than subjective pain ratings was an important part of the behavioural rehabilitation approach in this study. Patients often showed little variability in their pain ratings during inpatient rehabilitation, continuing to give high ratings despite showing positive affect during participation in therapy and leisure activities. The Maynard et al. (2010) study was not a controlled experiment, and therefore could not claim a causal relationship or dismantle the relative contributions of the multiple therapeutic components included in the rehabilitation protocol. Therefore, the authors recommended that prospective randomized controlled clinical trials are needed involving multiple centres implementing the same protocol.

### Case example

'Mark' was a 12-year-old African American male with obesity and spinal muscular dystrophy admitted to an inpatient rehabilitation unit following orthopaedic surgery. Postoperative complications included wound dehiscence (premature rupture of a wound along surgical suture) which required use of a wound vacuum-assisted closure (VAC) procedure to expedite healing. This case study was previously presented as a poster at the Annual Convention of the Association for Behavior Analysis (Kim et al., 2009). Mark was referred for behavioural psychology services secondary to his extreme anxiety and distress behaviour (e.g. screaming, crying, and pain verbalizations) related to this procedure early in admission.

Wound VAC procedures were completed by a physician and/or nurse every 2 to 3 days, with an additional staff member present to assist. Steps for the procedure included: removal of adhesive plastic sealant from wound site; removal of foam and drain tube; measurement of wound; lavage and removal of contamination and devitalized tissue; cutting foam dressing to approximate size of wound; insertion of dressing; application of adhesive plastic sealant; incision to sealant and insertion of suction tube, and activation of VAC system. Typical procedures last approximately 20 to 45 min.

Nursing staff completing the procedure recorded duration of procedure as well as Mark's behavioural responses on nursing flow sheets. Distress and/or delay behaviour (e.g. saying 'I'm not ready', asking questions unrelated to procedure, extending counting, e.g. 'two, two and a half ...') were rated as follows: (0) no observed distress or attempts to delay procedure; (1) minimal distress behaviour (e.g. some pain verbalizations during more difficult steps); easily consolable; few attempts to delay; (2) moderate distress behaviour (e.g. crying, verbalizing pain) and some attempts to delay throughout the procedure; able to recover upon procedure completion; and (3) severe distress (screaming, inconsolable crying) and frequent attempts to delay procedure.

Prior to psychology consultation, when nursing staff implemented an escape extinction protocol (i.e. simply proceeded with the necessary task) and Mark's distress and delay behaviours did not result in a break, high levels of distress were observed (Figure 51.1; Phase 1). During initial treatment (Figure 51.1; Phase 2), the introduction of verbal feedback and distraction (conversation and access to a TV show) were provided by behavioural psychology and child life staff. This intervention decreased distress behaviours; however, delay behaviours, in the form of asking for frequent breaks and attempting to extend counting during each step increased. Therefore, the next phase of treatment involved use of a patient-controlled break card in combination with verbal feedback and escape extinction. Specifically, Mark was provided with a card before beginning the procedure, and was informed that he could exchange this card to request a 1 min break. Apart from natural breaks (e.g. between steps, while staff cut the foam), Mark was only provided breaks when he appropriately used his break card. He was prompted to use his break card (if still available) if he verbally requested a break or exhibited anxious behaviours (e.g. 'stop' or 'I'm scared').

Providing Mark with a choice of when to exercise limited control over aversive stimulation and extinguishing delay behaviours resulted in markedly decreased distress and enabled staff to complete the change in a timely manner (Phase 3, Figure 51.1).

## CHAPTER 52

# Child life interventions in paediatric pain

Chantal K. LeBlanc and Christine T. Chambers

### Introduction

Child life specialists, as members of the health care team, are frequently involved in the assessment and management of pain in hospitalized children and children in emergency settings. Child life refers to a non-medical therapeutic service designed to address the developmental, educational, and psychosocial needs of paediatric patients. Child life specialists are professionals who 'promote effective coping through play, preparation, education, and self-expression activities. They provide emotional support for families, and encourage optimum development of children facing a broad range of challenging experiences, particularly those related to healthcare and hospitalization' (Child Life Council, 2012a), including painful procedures and coping with other types of pain (e.g. postoperative pain). This chapter provides an overview of the role of a child life specialist, including a historical perspective on the evolution of the field and current child life practices. The chapter then provides a summary of the specific contributions of child life specialists to pain assessment and management, including innovative uses of technology often facilitated by child life specialists.

### Historical context

The child life profession originates from a time when children were left at the hospital to be cared for by doctors, nurses, nuns, psychiatric personnel, and volunteers. Many hospitals severely restricted visits, even by parents, limiting these familiar, and often comforting, interactions to only a few hours per week (Thompson, 1989). There was often no contact with siblings. Recovery included long stays, immobilization, lack of stimulation, sterile environments, and no play space or educational support. Little information was shared with children about the reason for their hospital admission, diagnosis, or treatments, let alone preparation for procedures, surgeries or support for painful experiences (Jun-Tai, 2008; McCue and Hicks, 2007; Thompson, 1989). The lack of family visits and information shared was thought to protect patients and families. It was believed children would not be able to understand complex information and would become more upset if family members stayed for long periods of time and then left.

The negative impact of this vacuum psychosocial environment on children's health became evident including the link between lack of

stimulation and infant deaths (Spitz, 1945) and long-term psychological effects of hospitalization (Prugh et al., 1953). Hospitalized children were frequently withdrawn, quiet, and disengaged, coining the term 'hospitalism' (Spitz, 1945). Society at large began to develop a more sophisticated appreciation of the importance of cognitive, social, and emotional development during childhood. The effects of minimal stimulation, separation from family, and the potential trauma of hospitalization led to an appreciation that the experience of hospitalization put children at risk for significant emotional distress thereby impacting their overall health (Bowlby, 1952; Prugh et al., 1953; Spitz, 1945). This work prompted changes in health care (Thompson, 1989; Wojtasik and White, 2009), including the utilization of volunteers and staff, mostly women, to spend time with the children to engage them in play and learning. These individuals became known as 'play ladies', 'play teachers', or 'play leaders' (Rubin, 1992; Thompson, 1989). The Platt report, released in the UK in 1959 provided specific recommendations regarding the need for parents to be with their children while in hospital, the importance of specialized education and training of staff working with children, and the need for play and education during paediatric hospitalization (Anonymous, 1959). Changes in hospital visitation policies and programming and the realization of the need to meet the developmental and emotional needs of children during the provision of medical care (Barnes, 1995; Thompson, 1989; Wojtasik and White, 2009) provided the foundation for the child life profession.

Play programmes were noted as early as 1922 in the US and in 1936 in Canada, with nine identified programmes in North America by 1949. The 1960s and 1970s saw the coming together of professionals to organize associations such as the Association for the Wellbeing of Hospitalized Children and their Families in the US (later to be renamed the Association for the Care of Children's Health) and the Hospital Liaison Committee in the UK to lobby for stimulation and play for hospitalized children and specialized training to do this work. There are now over 480 programmes listed in the 2012 Child Life Council's Directory (Child Life Council, 2012b), in 18 countries around the world.

### Child life today

The child life profession is a new profession, stemming from the need for personnel with specific training to acknowledge and

address the developmental and psychosocial needs of hospitalized children. Child life has its roots in child development, psychology, recreation/leisure, education, sociology, and social science. Although there may be some overlap in professional roles with other psychosocial care providers, Thompson (1989) stresses the primary duty of the child life specialist is focusing on the developmental and psychosocial needs of the hospitalized child. In Canada, the US, and Kuwait, the title of 'child life specialist' is well recognized. In other parts of the world, this role is known as a 'hospital play specialist', 'hospital play staff', 'play leader', or 'child life therapist', however the philosophy, goals, and interventions are similar.

Child life specialists have specialized training, which in North America typically involves a minimum of a bachelor's degree in child life, child development, psychology or closely related field that incorporates a variety of coursework, including but not limited to child growth and development, function and development of play behaviours, family systems, behaviour management, child coping, psychology, and courses in child life methods. Additionally, successful completion of a child life internship, supervised by a certified child life specialist provides the minimum requirements to write the certification exam, offered through the Child Life Certifying Committee. Several countries (including Canada, the US, the UK, and New Zealand) offer credentialing processes for child life specialists to ensure specific and continued competencies in working with children in this field (Child Life Council, 2002; Hospital Play Specialist Association of Aotearoa/New Zealand, 2012).

Family centred care is a philosophy and way of interacting with families that is ingrained and intuitive to the child life specialist. As a result, child life specialists employ a collaborative approach to care, believing parents know their children best, should be true partners in care, and deserve to have information provided in a way they can understand. Cultural diversity is respected, focusing on the strengths of the family and its individuals, recognizing and respecting different coping styles, and being aware families require the appropriate supports to meet their needs (Shelton and Stepanek, 1994). Child life specialists work closely with all the members of the child's health care team to provide the best overall experience and outcomes for the child.

The role of child life specialists first originated in hospital-based paediatric inpatient units. However, many children outside of inpatient units experience repeated frightening or invasive procedures. As a result, child life specialists are involved in paediatric care in a number of settings, including: ambulatory clinics, diagnostic imaging (McGee, 2003), emergency department (Cavender et al., 2004; Gursky et al., 2010; Stevenson et al., 2005), sedation programme, day surgery (Brewer et al., 2006), mental health programmes (Breiner, 2003), neonatal intensive care, paediatric intensive care unit, critical care unit, laboratory medicine, children of adult inpatients (Thompson and Snow, 2009). A surgical event in day surgery or an urgent medical event in the emergency department can be painful and frightening for children and have profound effects on future encounters with health care providers. There are inequities in child life service delivery for different populations within and among hospitals and this continues to be a challenge.

Child life specialists provide valuable information about the child's perception and experience of medical events to the medical team. They are in a unique position because their role is typically viewed by the child and family as being non-threatening, non-invasive, and often 'fun'. They are able to quickly build rapport through

play and/or therapeutic dialogue, learn from the child/youth how they perceive and understand what is happening, clarify misconceptions and provide opportunities for questions, fears, or worries to be addressed. Strategies are then developed to assist with coping and adjustment to the situation, while ensuring a sense of mastery and control throughout the interventions. The child life specialist explores previous coping strategies and focuses on each family member's strengths, assessing the needs within the family (e.g. informational needs, emotional, parenting and/or sibling support needs) and partnering with them and other members of the team. When children and family members feel respected, engaged, and understood, they share their stories, their fears, worries, and needs, and become partners to make things better.

## Child life assessment and interventions

Child life specialists first assess the key variables which are known to impact coping and adjustment to health care experiences in order to develop a child life plan of care and goals for the interprofessional plan of care. There are many variables that can impact coping responses to hospitalization and health care interventions. This information is gathered from the health record, the child and family, those involved in the care, as well as through observation. The assessment is an ongoing process; it is dynamic, and changes as the information and needs change. This in turn influences the child life interventions to be provided. The assessment variables associated with a child and family's ability to cope with hospitalization include (Blount and Loiselle, 2009; Gaynard et al., 1990; Koller, 2008a):

1. Child variables: age/developmental level, temperament and coping responses.
2. Family variables: parental anxiety, parental involvement, marital status and education.
3. Medical experiences: number of invasive procedures and memory of these experiences.

There are a range of interventions child life specialists will provide. At the core of the interventions is the use of developmentally appropriate toys/activities and conversation to assist the child and family. Some of the interventions described are provided predominantly by child life specialists such as medical play while others are also commonly utilized by a variety of health professionals, for example cognitive and behavioural distraction. A child life plan of care is developed including one or more of the following interventions (Skinner and LeBlanc, 2002):

1. *Play*: child life specialists use play/activities as their primary tool in assessing and intervening with children and youth regardless of the reason for involvement. There are many functions of play for the child life specialist including assessment, teaching, and expression of feelings, modelling, preparation, distraction and sheer enjoyment. Play for children is universal, how they learn about the world, make sense of the world, develop skills to socialize, make decisions, and learn how their actions have an impact on themselves and others. Play provides freedom and a sense of mastery and control. Play helps children gain the developmental and psychosocial skills they need for life. It can also be a way to work through stressful experiences and is known to reduce a child's anxiety (Thompson, 1989). The child's ability to engage in their environment, their understanding of concepts

and experiences, their social skills, their communication and language skills, their perception of the world, their hope for a better day, and their ability to control aspects of their world (Jessee and Gaynard, 2009) is revealed through their play.

2. *Play programming*: child life specialists ensure the child has developmentally appropriate play materials and supplies to encourage active participation in play, in the room, in play areas or a teen lounge, as appropriate (could be another child life specialist or an assistant or volunteer).
3. *Health care/medical play*: health care play encompasses the use of medical supplies and equipment, toy medical kits, body outline dolls or demonstration dolls in directive or non-directive play and even the use of music, photography, or technology applications to express oneself in regard to the health care experience. This play may include expressive or creative arts using medical supplies; use of expressive arts to allow children to share their experience, express their feelings through art, puppetry, dramatic play, writing/journaling, photography, video, etc. Medical play typically specifies the use of medical supplies and equipment to re-enact medical experiences on a 'patient' such as a body outline doll, puppet, or favourite toy. This form of play allows for the expression of feelings, clarification of misconceptions; exploration of coping strategies and working through feelings associated with painful or frightening experiences (Ostrenga, 1980). Very young children, even under the age of 2 years, can participate in medical play. The type of medical supplies used and the decision to use real needles in the play is dependent upon the age/developmental level of the child, the child's emotional response to needles and the ability to maintain a safe play area.
4. *Developmental support*: child life specialists implement individualized play programme to support the maintenance or progression of developmental and psychosocial skills.
5. *Teaching*: child life specialists provide simple clear and developmentally appropriate explanations about the reason for admission, the machinery, the diagnosis, the treatment to be undertaken, or a forthcoming surgery.
6. *Preparation*: child life specialists provide the child and family with developmentally appropriate information through play and/or discussion; based on anticipated sensory experiences; exploration of stress points, exploration of coping strategies to be used; opportunity for rehearsal and development of a coping plan with the team as needed. By its very nature, this should occur prior to interventions and surgery, be based on the developmental and coping needs, and responses of the child/family.
7. *Procedural support*: child life specialists support the child and family during a stressful encounter/examination, medical intervention or procedure. This might include behavioural or cognitive distraction, breathing exercises, coaching parents, advocating for positions of comfort, relaxation techniques, positive reinforcement, providing information, visualization, or guided imagery.
8. *Therapeutic dialogue*: child life specialists encourage the expression of feelings, clarification of misconceptions; determine coping strategies and work through feelings associated with painful or frightening experiences.
9. *Family support*: child life specialists provide information to navigate the system of care, general emotional support; translate

medical jargon, liaise with the health care team, support brothers and sisters to cope effectively and help parents to recognize their child's coping style and support parenting roles.

These various interventions are adapted to fit the context of the work as the role of the child life specialist now extends beyond the hospital walls. Expertise and skills are utilized in rehabilitation centres (Davitt and Munn, 2008), dental offices (Glasrud and Feigal, 1984), community programmes (Chernoff et al., 2002), hospice programmes, funeral homes, specialized camps, the court system as well as consultation and support services for children of adult patients (American Academy of Pediatrics Child Life Council and Committee on Hospital Care, 2006; Hicks, 2008).

## The role of child life specialists in paediatric pain

During the early years of the child life profession, it was recognized that children's pain responses were greatly influenced by distress and anxiety while developmentally appropriate information could influence coping responses and recovery (Plank, 1962). As is summarized throughout this volume, research regarding children's experience of pain and the contributions of various pharmacological and non-pharmacological interventions to improve pain has advanced our knowledge significantly since the 1960s. However, there is considerable evidence supporting the fact hospitalized children experience significant pain and still do not receive optimal pain management (Stevens et al., 2011).

The following two case examples illustrate some of the varied interventions child life specialists provide in the management of children's pain, followed by a description of some of the most commonly employed child life interventions when pain is an issue.

### Case example: Jacob

Jacob is a 13-year-old admitted on the weekend with dehydration, 5 days post day surgery for tonsillectomy, articulating he was in a lot of pain and could not eat. Jacob was described by staff as a 'young' adolescent who was dramatic in his descriptions of his pain, was not eating or drinking well, and was likely going to need to stay for an additional night. Nurses reported that his mother was repeatedly voicing her concerns about her son's level of pain and was frustrated with the lack of pain control and intervention from staff.

Upon arrival, the child life specialist noted Jacob's affect was blunted; he reluctantly permitted her to enter the room, made fleeting eye contact, and initially answered questions quickly and hesitantly. His mother's posture was rigid and affect was neither welcoming nor engaging. When asked if he understood the reason for his admission, he stated his throat was bleeding, he couldn't drink, and the pain was unbearable. He repeatedly stated that the 'rotting flesh' in his throat gave his mouth an awful taste and he did not want to eat/drink because he did not want it to bleed again or to hurt more. His mother placed herself beside him on the bed, stroking his back, as he was curling into a fetal position.

### Assessment

The child life specialist gathered further information from Jacob in a non-threatening confidant manner while indicating there

were things that can be done to help with his pain. She explored his understanding of the surgery; the healing process post tonsillectomy; his typical coping style and previous successful strategies during stressful situations; his informational needs; his pain experience and what aspects of his experience were distressing; his personal interests and hobbies as well as expectation for improvement.

### Child life interventions

The child life specialist clarified misconceptions and explained the medical equipment in the room, IV and medication being infused, and the importance of fluid intake to help the tissue heal. The use of thought stopping and cognitive reframing strategies (positive self-talk) were modelled and practised by Jacob ('my throat tissue is healing and will keep getting better') while his mother's negative statements were also reframed and more positive comments were reinforced.

Jacob stated he was an actor and loved to perform in plays. He often utilized deep breathing strategies to support voice projection and also as a calming strategy before he performed. His knowledge about deep breathing to assist with his pain and anxiety was encouraged. Rehearsal of breathing in slowly through the nose and out through the mouth several times to permitted his body to develop a rhythm and allow the sensation of relaxation to begin. His mother was eager and willing to be his coach and prompt him to stop his negative thinking and to use the deep breathing method. By the end of the session both mother and child were more friendly, physically more relaxed, exuded confidence that things would improve, and decided to physically leave the room to explore the unit and the teen lounge which the child life specialist had encouraged.

### Case example: Carrie

Carrie is a 5-year-old girl referred to child life in anticipation of her upcoming bilateral ureter re-implantation surgery. The nurse recognized that Carrie would benefit from a child life preparation session and tour of the environment given that this was her first surgical experience.

### Assessment

The child life specialist contacted the family 2 weeks in advance to plan a preparation session prior to the surgery and to screen for potential stressors that might impact on child/family coping. She was a typically developing child, with a generally easy-going temperament and who generally likes to know what will happen with enough detail to help her predict the situation. Mother reported Carrie's only experience with medical interventions, other than vaccines, was a cystogram 3 months previously for which she was not provided advance preparation. Parents reported this procedure was anxiety provoking for her and her parents; Carrie cried with pain during the catheter insertion, was able to settle during the procedure but was distressed when it was time to release the contrast material from her bladder. When she learned of her upcoming surgery, she was upset and did not want to go back to the hospital for the operation. Mother reported Carrie typically copes well when provided with information and a plan of action.

Mother had been reading stories about going to the hospital and answering Carrie's questions, as they arose. Parents were planning to be in attendance throughout the admission and reported no other significant stressors.

### Interventions

Carrie and her mother met with the child life specialist and the pre-op nurse 1 week in advance of the surgery to learn what she would see, hear, smell, and experience in developmentally friendly language. The child life specialist offered Carrie a body outline doll for her to colour, as she wished, and offered to explain the medical equipment she would see. Carrie was interested in learning more. The child life specialist used Carrie's new hospital doll to demonstrate anaesthetic induction, explain the surgery in simple terms and 'perform' surgery, made a small opening, inserted external catheters to demonstrate what she would see upon waking, along with an IV and how the medicine goes through the IV to help her body get water and medicine to help with the 'ouch'. Carrie's body language and facial expressions were monitored closely to ensure the information was appropriate and to clarify any concerns, questions or misconceptions. Photographs of the surgical area, the hallways leading to the operating room (OR), the OR space and staff dressed in OR greens were shown after she indicated interest in seeing them. The family toured the surgical area and the inpatient unit, including the play areas and learned of the fun activities she would be able to do after the surgery.

After surgery, the child life specialist followed Carrie's progress. The first day post surgery, Carrie was playing contentedly in the bed, enjoying a craft left for her by the child life specialist. When asked, Carrie had no questions and stated the hardest part was 'it hurts when I move'. Strategies to cope with pain, such as the use of a pillow over the belly when moving, a warm blanket, slow breathing, counting, or using hand-held squeeze toys were discussed and she chose strategies she wanted to try. Daily visits occurred to assess her overall coping with the experience, monitoring for pain management issues, and promoting positive and fun activities in the playroom which motivated her to get up and walk. The child life specialist also provided procedural support for the removal of her catheters, once again preparing Carrie for what she would see, hear and feel as well as choosing distractions that would redirect her attention from the pain, this time by using applications on the iPad. Carrie's response post procedure was that 'it wasn't so bad'. Parents reported she slept well, and adjusted far better than anticipated; they felt confident and trusting of all members of the team given the coordinated approach to their daughter's care and pain management.

These two cases demonstrate the diverse nature of the interventions a child life specialist will provide. Building a strong rapport, conveying confidence and a belief that something can and will be done to decrease the pain are critical (Kuttner, 2010). Some of the most common interventions child life specialists provide for pain are summarized as follows.

### Preparing children for procedures

Children report pain and discomfort most frequently as one of the worst aspects of hospitalization (Lindeke et al., 2006). Providing clear and accurate information to children results in fewer negative

behaviours, reduces fear and anxiety, and leads to faster recovery postoperatively (Jaaniste et al., 2007; Koller, 2007). The key elements of effective preparation include: providing developmentally appropriate information, the opportunity to express emotions (fear, anxiety, and concerns), and the need for a trusting relationship (Koller, 2007). Early studies of preparatory programmes for parents (mothers) of children undergoing surgery using these same general principles showed significant decreases in parental anxiety and child coping as well (Mahaffy, 1965; Visintainer and Wolfer, 1975). The information should be child friendly, developmentally appropriate while using soft language versus words that provoke anxiety, for example, using the 'the doctor will make a small opening' versus a 'cut or incision'. Do not assume or insinuate something will hurt, but rather be honest about managing pain or discomfort should it occur. Balance the need to be honest while avoiding assumptions about how it will be experienced. Be aware of language and its double meaning, for example, for many children being 'put to sleep' reminds them of a pet that has been euthanized and may cause fear they may not awaken from the surgery, instead state 'the doctor will give you sleeping medicine'. Be prepared to address questions and misconceptions. Include not only specific and accurate information about the sequence of events (Jaaniste et al., 2007; Tak and van Bon, 2006), but also the rationale for the procedure (Campbell et al., 1995; Koller, 2007; Patterson and Ware, 1988) and the sensory information they will see, hear, taste, or smell (Koller, 2007; Suls and Wan, 1989). The preparation literature also consistently promotes the preparation for and modelling of coping strategies to cope with painful experiences (Jaaniste et al., 2007; LaMontagne et al., 2003a, 2003b; Patterson and Ware, 1988; Spafford et al., 2002).

In Carrie's case example, notice the key preparatory elements are present. Carrie was provided specific information through play and visual aids, in language she could understand. She was offered opportunities for questions; affective responses were monitored and the amount of information provided was guided by her throughout the session. Given her developmental level, information regarding anticipated pain was minimal; however, this was addressed postoperatively, with concrete strategies to rehearse and implement postoperatively as well as during procedures.

## Distraction

The use of distraction during painful procedures is an effective strategy in reducing anxiety, distress, and paediatric pain (Uman et al., 2006). Distraction is the shifting of attention away from the painful or anxiety provoking stimuli to something more pleasant, interactive, or interesting. Distraction can be used with children as young as 10 months of age, can be cognitive in nature, and/or behaviourally focused (Kuttner, 2010). Some examples include non-procedural conversation, counting, bubble blowing, playing 'I Spy With my Little Eye', using pop-up books, the use of stress balls or hand held manipulative, and applications on an iPad. Providing a child with choices about the kind of distraction toys or activities provides a sense of control. Often children will use multiple distraction activities during a procedure or stressful experience. The distraction item(s) or activity(ies) must be highly engaging, be easy to use, and match the child's interest, developmental level, and ability (see Table 52.1 for examples). Younger children tend to need more active distracters and coach involvement whereas older children will often choose more passive distracters such as

music or videogame systems (Cavender et al., 2004; Sinha et al., 2006). Distraction is often used in conjunction with preparation and information sharing. Distraction is more effective with mild to moderate pain and can be particularly effective for children with chronic conditions (Kuttner, 2010).

## Parent/staff coaching in the use of distraction

A distraction coach (parent or health professional) is an important role during any painful procedure. Child life specialists are trained in this type of intervention, are recommended in the emergency department (ED) literature on pain management (Madhok et al., 2011; Zempsky and Cravero 2004) and can be helpful in training others in these strategies (Cregin et al., 2008; Zempsky and Cravero 2004). A child's attention may direct itself to the painful procedure at intensely painful moments or with new sensory experiences. With support and education, parents or other health professionals can become effective distraction coaches (Kleiber et al., 2007). Engaging parents of children with long-term or chronic illness in this skill development is important in order to minimize dependency on health professionals, instil confidence and decrease parental anxiety caused by feelings of helplessness and guilt. Parents must be provided with information and positive feedback about their skills (Cavender et al., 2004; Kleiber et al., 2007).

In Jacob's case example, Jacob's mother did not initially engage with the child life specialist, but once she recognized Jacob was receiving concrete and practical information and strategies she recognized were useful for both of them, she was able to engage and accept a role of coach.

## Breathing

Teaching children and parents slow, rhythmic breathing from the diaphragm rather than the chest is a simple and effective strategy. Children can be engaged in pretending to blow out candles, or blowing like the wind to move clouds in the sky, using party blowers, blowing bubbles, pretending to inflate or deflate a tyre or a balloon through inhaling/exhaling. Breathing in through the nose and out through the mouth, imagining the breath going down to the belly also give the child a visual image. One can also ask the child to imagine all their worries are collected in their belly and to blow them away, until they get smaller and smaller.

Jacob's case example demonstrates how using multiple strategies, thought stopping, positive self-statements, cognitive reframing with the addition of deep breathing can be very effective. Many children require a 'tool box' of skills and strategies.

## Positive reinforcement

Positive reinforcement can come in the form of praise or in the form of a tangible reward (sticker/toy). Providing clear and specific positive statements is necessary. Making a statement 'Good job' will not likely encourage the reoccurrence of the specific behaviour desired, whereas 'You did a great job sitting still like a statue ... that really helped a lot' provides a clear understanding of the behaviour which was helpful.

The use of tangible rewards must be clearly defined by staff and family. For example, does the child receive a sticker for a specific, previously determined behaviour and does not receive it if the behaviour does not occur, or does the child receive the sticker because the procedure is complete or alternatively as a distracter

**Table 52.1** Common distraction strategies used by child life specialists:—developmentally based distraction strategies

Age	Developmental issues	Behavioural/distraction techniques
Infant Birth to 2 years	<ol style="list-style-type: none"> <li>1. Caregiver attachment</li> <li>2. Basic needs need to be met in a consistent manner</li> <li>3. Create calm environment, low lighting, low voice tone</li> <li>4. near the end of procedure? It is important to be clear since one does not wish to reward unwanted behaviour.

### Positioning for comfort

Children, especially preschool children, feel more vulnerable and fearful when lying in a supine position and this can be an immediate trigger that evokes a combative and/or uncooperative response (Cavender et al., 2004). Different positions can be utilized which allow the child to remain seated on the chair, stretcher, parent's lap or between the parent's legs (Stephens et al., 1999) while providing access for procedures and a comforting hold from parents. With the use of positions of comfort, children were observed by health professionals and parents alike to be less fearful (Cavender et al., 2004) and parents reported greater satisfaction (Sparks et al., 2007).

### Modelling and rehearsal

Modelling is the demonstration of positive coping behaviours during a mock procedure by someone else. Child life specialists will often model breathing strategies or a desired behaviour for a procedure, such as 'keeping your arm still like a statue' or the use of physical strategies such as squeezing a stress toy. Once modelled, practice and positive reinforcement for the desired behaviour will increase its use.

In Jacob's case example, Jacob was shown how to breathe slowly and deeply (modelling) then was rehearsed with his mother. His mother agreed to be his coach and prompted him to use this breathing technique if she noted escalating anxiety or pain.

### Therapeutic play

Koller's (2008b) review of therapeutic play in paediatric health care states 'therapeutic play refers to specialized activities that are developmentally supportive and facilitate the emotional well-being of a pediatric patient' and its focus is on the 'promotion of continuing 'normal development' while enabling children to respond more effectively to difficult situations such as medical experiences' (p. 3). This form of play can take many forms—puppet shows, dramatic play, creative or expressive art or medically focused play. Given that it is an integral part of a child life specialist's practice, more research evidence is needed in support of the efficacy of therapeutic play.

### Health care play/medical play

Children with serious and/or chronic illnesses, who experience many painful procedures, will often repeatedly request medical

**Figure 52.1** Image of a medical play session. Photographer: Copyright © Gary Yokoyama, 1999 (December 11). Making a scary world a bit safer. Republished with permission of *The Hamilton Spectator*.

play focusing on the re-enactment of interventions with the use of a body outline doll and medical supplies. This allows the exploration of the child's perception of their experiences, clarification of misconceptions or misunderstandings (Ostrenga 1980) and/or reinforcement of information previously provided during their illness (see Figure 52.1). It also permits the opportunity for the child life specialist to return and continue with this modality to reassess or debrief with the child after their experience. Requests for repeated medical play sessions will typically taper off and may resurface at stressful periods.

Medical play was used during the preparation in Carrie's case along with the provision of developmentally appropriate information. The offer of a body outline doll and an opportunity to explore the medical kit and supplies provided Carrie with a sense of control and mastery of the situation.

### Thought-stopping/coping self-statements/cognitive reframing

Thought-stopping can be very effective when children find their mind repeatedly thinking the same negative statements or images. Children can recognize this and be encouraged to take control of their brain and tell it what to do. The child repeats 'stop' or a similar statement during times of distress/pain, to block out negative thoughts. Often, child life specialists will then encourage the child to choose a positive thought, strong encouraging statement such as, 'I can do this' or 'This will be over soon'. This can be easily taught and reinforced.

In reviewing Jacob's case, the child life specialist used these strategies with Jacob. Given his vivid imagination about the 'rotting flesh' it was important to use his words and re-phrase the way he perceived the healing process 'my throat tissue is healing and will keep getting better.' This became a mantra he rehearsed and his mother prompted him if he went back to his negative verbalizations.

### Memory change

After a procedure is complete, it is valuable to assess the child and parents' perceptions of the experience. Sometimes, children will indicate they did not feel it went well: 'I cried' or 'I wasn't brave' or 'it hurt a lot' are common perceptions. Exploring the child's perceptions and then helping the child to reframe negative memories of the procedure into positive ones, 'Lots of boys and girls and even big people cry when something hurts (or is hard work), you stayed so still which really helped make the IV go in easier'; 'Being brave means doing something even though it's scary. You did it! You let the nurses access your Port-a-Cath™ even though it was scary and was uncomfortable', 'I noticed this time, that you didn't move your arm when the tube went in for the IV, you were able to do it, even though it was uncomfortable, I bet next time it won't bother you as much'.

### The evidence

As illustrated in the clinical examples above, child life specialists frequently employ a number of evidence-based non-pharmacological pain management strategies. In a large scale survey of over 600 child life specialists in North America, Bandstra and colleagues (2008) found that over 65% of child life specialists reported providing pain management interventions for at least 50% of their patients. The most commonly reported non-pharmacological pain management strategies used by child life specialists were: providing information/preparation, comforting/reassurance, positive reinforcement, and behavioural distraction followed closely by therapeutic play, breathing exercises, and medical play (Bandstra et al., 2008). Consistent with their training and philosophy, child life specialists deliver these interventions in a developmentally appropriate manner, infused with various aspects of play. The literature indicates reassurance can increase anxiety and decrease coping responses to pain (McMurtry et al., 2010) thus further study regarding the child life specialists' use of and/or interpretation of 'reassurance' is warranted. Of note, child life specialists who were certified, those with greater involvement with children who required assistance with pain management, and those who perceived they had a greater level of knowledge

and skills in paediatric pain management were more likely to use evidence-based non-pharmacological pain management strategies (Bandstra et al., 2008). While child life specialists in this survey reported training in non-pharmacological interventions, they expressed a high degree of interest in receiving additional training in non-pharmacological pain management interventions.

There is a growing body of literature supporting the role of child life specialists in implementing non-pharmacological interventions for children and families experiencing painful interventions (Brewer et al., 2006; Eldridge and Kennedy 2010; Gursky et al., 2010; Madhok et al., 2011; Zempsky and Cravero 2004). The most significant body of evidence is found in studies of child life interventions in the ED. Gursky and colleagues' (2010) study in the ED demonstrates that non-pharmacological interventions such as preparation and distraction provided by child life specialists can decrease observed distress behaviours during suturing, that parents perceive their child is less distressed and they are more satisfied with services provided in the ED. Alcock et al. (1985) found decreased fear with child life interventions that included preparation and teaching of coping strategies and emotional support for suturing while Cavender et al. (2004) noted decreased fear with preparation, positioning for comfort, and the use of distraction strategies. Interestingly, the child's assessment of their pain during these noted procedures has not been found to be decreased with the interventions. Parent-reported perception of pain distress has been found by Sinha et al. (2006) and Gursky et al. (2010) to decrease with child life intervention of preparation and use of distraction. There is evidence to suggest that child life interventions impact satisfaction rates in the ED as well (Alcock et al., 1985; Browning and Stroud, 2008; Gursky et al., 2010). Child life specialists are in a pivotal role to teach/prepare patients, parents and staff and provide interventions to assist with pain management (Cregin et al., 2008; Zempsky and Cravero, 2004); decrease anxiety and pain perception (Alcock et al., 1985; Gursky et al., 2010); and support family participation (Cavender et al., 2004; Stephens et al., 1999).

### Innovative use of technology

Children and families access the Internet for health information, prior to seeing health professionals, view videos of machinery, and watch YouTube™ videos of professionals and tests, of other families talking about procedures and what the experience will be like from an experiential and sensory perspective. Many families arrive with personal electronic devices and anticipate Internet access during health care visits. Children, youth, and families can utilize these devices to aid with coping; help minimize feelings of isolation and disconnection from family, friends and school; provide diversion from the monotony of long days and provide distraction from invasive, distressing, or painful interventions.

Child life specialists are integrating portable music devices and Wi-Fi tablets into their day-to-day practice. Closed-circuit TV is being utilized for therapeutic goal development with children/youth with the outcome of creating educational and therapeutic videos to educate and teach children/youth how to deal with worries, what to do if they have pain, how to talk to health professionals, and what happens when you have a specific test.

Tablets are replacing paper copies of preparation photos and books. The multitude of applications such as I Hear Ewe, Angry

Birds, Cookie Doodle as well as audio books, music and YouTube™ videos can provide a large repertoire of potential distraction activities (McQueen et al., 2012). Staff and families report increased success at maintaining attention for children across the age spectrum. This one tool in the child life specialists 'tool box' can provide hundreds of activities, minimizing the need to anticipate and bring a bagful of activities for any given child/youth.

Children/youth with chronic physical or mental illness are at risk of social isolation which can impact self-esteem, self-perception and overall coping with diagnosis and treatment. The advent of Starbright World® (<[http://www.starbrightworld.org/default\\_login.aspx?ReturnURL=%2fhome.aspx](http://www.starbrightworld.org/default_login.aspx?ReturnURL=%2fhome.aspx)>) and

Upopolis™ (<<https://www.upopolis.com/webconcepteur/web/upopolis>>) are examples of online Intranet support programmes that youth with chronic illness can meet others in similar situations while in a safe, closed system, on the Internet. Both programs contain health information written for children and youth in developmentally appropriate language. Studies of Starbright World® indicate improvements in mood and pain responses in children/youth and nearly significant results for anxiety (Davis et al., 2004; Rode et al., 1998).

The use of high-definition and augmentative reality will likely launch technology to a new level of interactive capacity, with growing evidence supporting the efficacy of these approaches for the management of pain in children (Kipping et al., 2012; Miller et al., 2009). This may have even more success in distracting children from distressing or painful stimuli. Research into the use of all of these devices has barely begun; however, clinically there is a great deal of excitement about the perceived success of such applications in the area of teaching, preparation, procedural support, and expressive activities.

## Conclusion

Child life specialists play an important role in the assessment and management of pain in children in a variety of settings throughout the hospital as well as other health care settings. Their expertise and unique relationship with the child and family can provide a rich source of information to the interdisciplinary medical team in order to promote effective pain assessment and management and to provide the best overall collaborative and effective care for children. Child life specialists make major clinical contributions in terms of their delivery of non-pharmacological pain management strategies, with a focus on preparation, rehearsal, behavioural and cognitive distraction, and physical interventions such as positioning for comfort. Despite their considerable involvement in pain assessment and management, it has only been in recent years that empirical research on the role of child life specialists in paediatric pain had begun to emerge in the literature. Until further research emerges, the use of theoretical frameworks and evidence based literature continues to be the foundation of child life clinical practice. It is critical for the profession to continue to question the historical assumptions related to child life interventions and seek best evidence and research to ensure efficient and effective practice.

There is a need for interprofessional collaboration, training, and research in the field of paediatric pain in an effort to translate the knowledge that exists into daily practice. However, it will also be important for future studies to address the added benefit

of involving child life specialists in paediatric pain care, and for studies to further our understanding of how child life specialists can provide maximum benefit to children in pain and their families.

## CHAPTER 53

# Procedural pain distraction

Lindsey L. Cohen, Laura A. Cousins,  
and Sarah R. Martin

### Summary

This chapter provides a brief overview of paediatric procedural pain, highlighting some of the negative repercussions of untreated pain. The behavioural approach of distraction is covered in depth, starting with the theoretical underpinnings of this pain management intervention and then summarizing the distraction literature across children's pain during immunizations, venous access, burn debridement and treatment, and cancer treatments. The chapter concludes with a discussion of some of the other reviews of this literature as well as clinical and research considerations when examining distraction for paediatric pain management.

### Overview of paediatric procedural pain

Starting at birth and continuing through development, children will undergo a host of routine as well as unplanned invasive medical procedures. As an example, the World Health Organization (WHO) recommends approximately 20 to 30 vaccinations by 6 years of age (WHO, 2012). Additional vaccines for encephalitis, yellow fever, typhoid, cholera, meningococcal, rabies, mumps, and influenza are recommended for certain geographic locations and high-risk populations (WHO, 2012). The majority of these vaccinations are administered via intramuscular injections. Beyond routine procedures, roughly 78% of children admitted to hospitals will undergo at least one medical procedure, typically involving needles (e.g. venous access; Stevens et al., 2011). Although immunizations, venous access, and other invasive medical events are critical for children's health, children find needle procedures anxiety-provoking and painful (e.g. Jacobsen et al., 2001; Schechter et al., 2007). For example, data suggest that over half of children require physical restraint during routine immunizations (Blount et al., 1992).

Although invasive events are a necessary aspect of appropriate health care, there can be a host of sequelae. First, the high pain intensity associated with routine and unplanned procedures can contribute to immediate fear and anxiety, in turn heightening the pain experience in a cyclical fashion (McGrath, 1994; Rhudy and Meagher, 2003). The child's negative physical and affective reactions might lead to disruptive behaviour (e.g. Bijttebier and Vertommen, 1998; Broome et al., 1990) and contribute to parents' anxiety (e.g. Kuppenheimer and Brown, 2002). Second, these negative sensations and emotions associated with medical care are likely

to influence long-term health care attitudes and behaviour (Chen et al., 2000; Jones et al., 2008; Kennedy et al., 2008; Pate et al., 1996; Taddio et al., 2009). On a physiological level, early pain might alter the pain-processing neuronal circuitry leading to heightened pain perception in the future (e.g. Hermann et al., 2006; Ruda et al., 2000; Taddio et al., 1997).

### Behavioural treatment of paediatric procedural pain

Given the immediate and delayed negative effects of acute paediatric procedures, analgesics and sedatives have been used to provide some pain relief; however, these approaches have failed to consistently eliminate pain and often do little to decrease fear or anxiety. In addition, pharmacological approaches are less frequently employed for venous access and immunization injections, likely due to the brevity of the procedure. Fortunately, researchers and clinicians have employed behavioural approaches to minimize the negative physical and emotional aspects of routine invasive medical procedures. Reviews of the literature suggest that—generally speaking—behavioural approaches are beneficial to children facing distressing and painful medical events (e.g. Pillai Riddell et al., 2011; Powers, 1999; Uman et al., 2010). Unpacking these reviews quickly reveals that the 'devil is in the details'; there are many different behavioural approaches used with a variety of acute medical procedures to help a diversity of children. Behavioural interventions range from fairly circumscribed approaches (e.g. having children cough during venous access; Wallace et al., 2010) to multicomponent packages (e.g. imagery, physical vibration stimulation, distraction; Berberich and Landman, 2009); the acute pain literature spans experimental analogous approaches (e.g. cold-pressor; Dahlquist et al., 2007) to routine brief procedures (e.g. venous access; Cohen, 2008) to more invasive and severe medical events (e.g. burn debridement; Hoffman et al., 2000); and patients are diverse in a number of important ways (e.g. age, gender, culture, temperament, prior experience). In an attempt to provide some depth in this broad topic, this chapter will focus only on the use of distraction for a sample of children's acute invasive medical procedures. Other psychological interventions (e.g. cognitive behavioural therapies (Logan et al., Chapter 50), operant based treatment (Slifer et al., Chapter 51), bio-feedback (Stinson and Jibb, Chapter 55)) and physical interventions

(e.g. physical therapy (Tupper et al., Chapter 56), occupational therapy (Holsti et al., Chapter 57)) are fully described in other chapters in this volume.

## **Distraction for paediatric procedural pain**

### **Theories of distraction mechanisms**

Distraction is generally defined as shifting attention from one source onto the new one, whether it be internal (e.g. imagery) or external (e.g. watching a movie). Within the field of paediatric procedural pain management, distraction has been described as redirecting a child's attention away from anxiety-provoking painful medical stimuli, such as needles, to engaging or enjoyable stimuli (Kleiber and McCarthy, 2006; Sander et al., 2002).

Physiologically, theorists propose that distraction or selective attention may enhance electrical activity in the brain in response to a distraction task (i.e. the attended-to stimulus) as compared to the noxious or painful stimulus (i.e. the ignored stimuli). Several studies have shown that distraction tasks reduce the activity of brain areas known to process pain stimuli (Bantick et al., 2002; Frankenstein et al., 2001; Petrovic et al., 2000). According to the gate control theory of pain (Melzack and Wall, 1965; Wall, 1978), the substantia gelatinosa serves as a gate control system by modulating ascending impulses from peripheral nerves before they are perceived as pain by the cerebral cortex. When external (e.g. massage) and internal non-nociceptive input (e.g. anxiety) surpass nociceptive (pain) input, the gate may partially or entirely shut, blocking the pain signal. A distraction intervention is thus hypothesized to mitigate pain through descending non-nociceptive impulses that inhibit the chief nociceptive signal, altering nociceptive responses (Melzack and Wall, 1965), although it remains unknown how specific characteristics of distraction stimuli may alter gate modulation.

Attention can also be operationalized and assessed cognitively. A prominent cognitive theory, limited attentional capacity theory (LCT; McCaul and Malott, 1984), relies on two assumptions to support the analgesic effect of distraction. The first assumption defines nociception as an intentional process that requires effort and attentional focus on the eliciting stimulus. The second assumption posits that attentional capacity is limited and nociceptive stimuli will not be perceived if an individual's attentional focus is completely diverted to a specific task. Since undivided attention is difficult to achieve, distraction is less effective with a noxious stimulus of greater intensity (e.g. burn debridement) or with a distraction stimulus of lesser intensity (e.g. conversation on a topic that is not unique, such as school activities). LCT predicts that distraction will be more effective than placebo and redefinitional strategies (e.g. cognitive restructuring of fear) at low levels of noxious stimulus intensity. Additionally, distraction will be more effective in managing mild levels of pain and distraction stimuli that require greater attentional capacity will inhibit more attention needed to perceive pain (McCaul and Malott, 1984). Due to the theory's circular assumptions and elementary reliance on one domain of information processing, a more advanced theory, multiple attentional resource theory (MRT; Wickens, 1984, 2002) developed.

MRT proposes three distinct domains of information-processing capacity, including the perceptual demands of a task, tasks requiring a spatially driven manual response or verbal response, and tasks perceived visually versus aurally. According to this theory, the level of interference when processing other stimuli is dependent upon

the degree to which two competing tasks utilize the same information-processing domain (Wickens, 1984). Researchers suggest that the level of pain perception results from how information is processed according to the three domains, with detection of pain primarily occupying the perceptual and spatial resources (Johnson et al., 1998). In contrast to LCT, MRT predicts that distraction is most effective if engaging the same system as pain (i.e. perceptual). Thus, a distraction such as a vibrating device placed on the arm (e.g. Berberich and Landman, 2009; Baxter et al., 2011) is theorized to optimize interference with pain related to an injection in the same arm.

Finally, attention can be operationalized and assessed behaviourally, as visual or auditory orienting responses to external stimuli (Pavlov, 1927). Mowrer's two-factor learning theory (Mowrer, 1947) asserts that both classical conditioning and instrumental conditioning play a significant role in pain responsivity. In classical conditioning, a neutral stimulus, such as medical equipment, accompanies a pain-eliciting unconditioned stimulus (UCS), which consistently produces an unconditioned response (UCR) (e.g. pulling away). Due to this association, the neutral stimulus becomes a conditioned stimulus (CS) that elicits a conditioned response (CR) of fear or anxiety preceding the UCS. In instrumental conditioning, avoidant responding (e.g. crying) follows the CR and persists through negative reinforcement, such as a decrease in fear, as a means of avoiding the CS and UCS. Cohen (2002) suggests that distraction tasks deter attention away from painful stimuli and conditioned stimuli that also evoke distress, ultimately reducing the CR and UCR that develop from painful paediatric procedures (i.e. a conditioned fear response). Distraction may also produce behaviours incompatible with distress, such as relaxation or laughter. Despite the lack of a unifying theoretical framework for distraction mechanisms (DeMore and Cohen, 2005), distraction remains one of the most prevalent forms of behavioural pain management among health care professionals. This is likely due to its ease of use.

### **Efficacy of distraction for paediatric procedural pain**

When reviewing the paediatric pain literature, it should be noted that there is great variability in what is described as distraction in form, function, and efficacy. For example, a cartoon shown to a child during a procedure might serve the intended purpose of inducing a positive-mood state incompatible with distress, engaging a child in mathematical computations might occupy attentional resources, and a virtual-reality head-mounted display might effectively remove all medical stimuli from the visual and auditory fields. Thus, although all of these approaches can be described as 'distraction', they might be quite different in topography and mechanism of effect. To further complicate the issues, individual characteristics of the child (e.g. age, temperament, coping style) might react with the distraction such that it assumes a different function. For example, some children might find the latest rap song to be an enjoyable distraction from the threatening sound of a dental drill, while others might prefer the drill. The variability and subsequent effectiveness of distraction is highlighted by the efforts of Kleiber and colleagues who have developed a scale that measures both the quantity and quality of parent-provided distraction (Kleiber et al., 2007; McCarthy et al., 2010a, 2010b). Given all of these caveats about distraction for acute paediatric procedural pain, it is not surprising that results in the paediatric pain literature are inconsistent (e.g. Carlson et al., 2000; Cramer-Berness, 2007). Acknowledging that

there is variability in the effects of distraction within and between studies, the subsequent sections will highlight the use of distraction in different common acute paediatric procedures. In addition, given the large number of paediatric procedural pain studies that incorporate distraction, this review will highlight some of the studies that exemplify unique aspects of the approach.

### Immunizations

Immunization schedules vary by country, but it is generally recommended that children receive 20 to 30 vaccinations by 6 years of age (WHO, 2012). The majority of these vaccinations are administered via intramuscular injection, which children find anxiety-provoking and painful (e.g. Jacobsen et al., 2001). As paediatric intramuscular immunization injections remain the most common painful paediatric medical procedures in health care settings, distraction has been evaluated in a number of studies (Schechter et al., 2007). For example, a series of studies evaluating nurse-led movie distraction during immunizations demonstrated that distraction was generally beneficial to infants (Cohen, 2002; Cohen et al., 2006), preschoolers (Cohen et al., 1997), and preadolescents (Cohen et al., 1999). However, findings were not consistent across all measures or all phases of the procedure. Wallace et al. (2010) evaluated the efficacy of the 'cough trick,' requiring 4- to 5-year-olds and 11- to 13-year-olds to provide several coughs prior to and coinciding with immunization injections. This technique is thought to distract children from the immunization by focusing on coughing when prompted and possibly creating antagonistic sensations developed from the noise and feeling of the cough. Of note, the cough trick was effective for Hispanic white or non-Hispanic white children ( $t_{33} = -2.86, p < 0.01$ ), but did not prove beneficial to non-Hispanic black children.

Berberich and Landman (2009) included distraction in a package to reduce pain in pre-schoolers receiving immunizations. The intervention included a multipronged arm gripper, topical analgesic, and a vibrating instrument on the opposite arm. The children were encouraged to guess when the vibrating device reached their arm. Results supported the intervention across measures (self-report scores,  $p < 0.0013$ ; parent report scores,  $p < 0.0002$ ; observational coding scores comparing baseline to completion of immunization series,  $p < 0.0001$ ), but it is unclear which are the critical ingredients in package interventions such as this (Cohen, 2010).

In a systematic review of 20 randomized controlled trials (RCTs), Chambers et al. (2009) determined that both child-directed (e.g. cartoons, music) and nurse-led (e.g. trained to distraction with movies or toys) distraction were effective in mitigating pain and distress during child immunizations, whereas evidence remained inconclusive for parent-led (e.g. trained to distract with movies or toys) distraction. Chambers et al. noted that distraction with age-appropriate toys was the only psychological intervention examined in the review that can be applied to all age groups due to the ability to select toys suitable for infants, children, or adolescents. A review by DeMore and Cohen (2005) concluded that distraction is both a time- and cost-efficient strategy for immunizations and that it effectively reduces children's injection pain. Although a variety of distracters were used in the studies evaluated, the most commonly employed distraction stimuli were playing cartoon movies, non-procedural talk, and having the child listen to music. Distraction strategies that either required an overt response from the child or involved multiple sensory modalities were most effective.

To date, the immunization pain literature has predominantly focused on preschool-aged children due to the numerous vaccinations needed for school entry and their high level of reported distress. Although a few studies support the use of distraction for infant (Cohen, 2002; Cohen et al., 2006; Felt et al., 2000) and pre-adolescent participant samples (e.g. Cohen et al., 1999), further research tailored to these age groups is warranted (Cramer-Berness, 2007; Schechter et al., 2007). Additionally, most participant samples have consisted of Caucasian mother-child dyads, limiting the generalizability of findings to other races, ethnicities, and caregivers (DeMore and Cohen, 2005). Unfortunately, parents and health care professionals still exhibit a poor understanding of the value in employing distraction for immunization pain relief (Chambers et al., 2009).

### Venous access

Venous access has been identified as one of the medical procedures most feared by children (Carlson et al., 2000). In one of the few studies comparing distraction interventions, MacLaren and Cohen (2005) found that passive distraction (viewing movies) was more effective than active distraction (responding to games on an electronic toy) during paediatric venous access. Bellieni et al. (2006) also found that passive distraction (watching a TV cartoon) was more effective than active distraction during venepuncture. That said, a study evaluating children's pain tolerance during a cold pressor suggests that active distraction (playing a videogame) might be more effective than passive distraction (watching a videogame) (Wohlheiter and Dahlquist, in press).

Several studies support the efficacy of audiovisual distraction techniques, through the form of animated cartoons, in diverting children's attention from venepuncture pain. Yoo et al. (2011) found an animation distraction intervention effective in reducing self-reported pain, behavioural pain responses, and serum cortisol and glucose levels in preschool-aged children during venepuncture in Seoul, Korea. Wang et al. (2008) found cartoon videos equally effective as other routine psychological interventions (i.e. explaining, therapeutic touch, encouragement, and guided imagery) in reducing self-reported pain, enhancing patient cooperation, and heightening the success rate of venepuncture procedures. Researchers also suggest that animation distraction is both simple to administer and could be easily integrated into health care settings.

Although studies remain less conclusive about caregiver participation, some suggest that distraction education for parents prior to venepuncture may be valuable (Kleiber et al., 2001). Kleiber et al. (2001) compared parent-child dyads in a control group to those in a distraction education group across two phases of venepuncture, procedural preparation and needle insertion. Parents in the distraction education group employed significantly more distraction during both phases compared to parents in the control group and children in the distraction condition exhibited less distress during the two procedural phases than children in the control condition. In a review of the literature, Cohen (2008) suggested that distraction is recommended for paediatric venous access, particularly for children aged 7 years or younger, due to its empirical support, minimal risks, and cost- and time-effectiveness.

### Burn debridement and treatment

Childhood burns represent one of the most physically and emotionally traumatic injuries (Benjamin and Herndon, 2002; Hettiaratchy and Dziewulski, 2004), which often result in long-standing pain and distress (Fitzgerald, 2005; Passaretti and Billmire, 2003;

Schechter et al., 1993). Increasing research has focused on evaluating behavioural approaches for pain management for burn treatment procedures (e.g. skin debridement; de Jong et al., 2007) given that pharmacological analgesic methods often prove inadequate (e.g. Hoffman et al., 2004; for a review, see Morris et al., 2009).

The distraction literature for burn treatment procedures often involves sophisticated—and potentially highly engaging—interventions (e.g. virtual reality; Hoffman et al., 2004). This is likely related to the rationale that it is challenging to distract a child from the severe pain that is associated with burn treatment pain. To exemplify, in comparison to standard distraction and hand-held video game distraction, multi-modal distraction used for procedural preparation and distraction during dressing changes significantly reduced pain and the duration of three dressing changes among children in a paediatric burns outpatient clinic (Miller et al., 2010). This hand-held device effectively engaged children in an interactive procedural preparation story or a touch and find interactive distraction story during the dressing change procedure. In a study of children's distress related to burn-dressing changes, Mott et al. (2008) compared 'augmented reality' (akin to virtual reality although uses overlays of virtual images onto the actual world) to basic cognitive therapy. Parents' ratings and children's self-reports indicated that the augmented reality distraction was superior to control for burn treatment pain relief.

Distraction, in the form of immersive virtual reality, has also been shown effective as an adjunctive analgesic for paediatric burn patients (Schmitt et al., 2011). Participants randomly assigned to the immersive virtual reality group (i.e. SnowWorld virtual environment) reported significant decreases in pain ( $p < 0.05$ ) and improved affect when performing range-of-motion exercises on the first day of the study, which persisted across the 5 days of physical therapy sessions. Similar positive results were demonstrated by Das et al. (2005) in a study of virtual reality distraction for 5- to 18-year-olds undergoing burn treatment. Similarly, Hoffman et al. (2000) showed that virtual reality distraction reduced pain scores, anxiety, and time spent thinking about pain for two adolescents undergoing wound care for severe burns. Researchers in this area suggest that distraction should be tailored to individual patient needs, that the potency or engaging quality of the distraction should match the severity of the procedural pain, and lower cost and greater portability would provide more widespread dissemination of the interventions (Hoffman et al., 2011).

### Cancer treatments

During cancer treatment, children undergo multiple invasive medical procedures including venous port access, lumbar puncture, and venepuncture; the treatments are often described as the most distressing part of the disease (Hedstrom et al., 2003). Despite advances in pharmacological approaches for pain management, there continues to be a need for additional pain and anxiety relief (e.g. Varni et al., 2004). A number of distraction interventions have been effective for the procedures faced by this population. For example, Gershon et al. (2004) found that a virtual gorilla distraction exhibit effectively lowered distress in a small sample of 7- to 19-year-olds with cancer undergoing port access procedures. Windich-Biermeier et al. (2007) had 5- to 18-year-old oncology patients select from a variety of distraction stimuli (e.g. books, bubbles, hand-held games) and showed that distraction lowered their fear and distress during port access and venous access procedures.

In a study of music distraction, researchers found this treatment effective in lowering anxiety in children with cancer receiving lumbar punctures (Nhan Nguyen et al., 2010). Although not described as distraction, commonly used hypnosis and imagery techniques are arguably forms of internally shifting attention from a noxious stimulus to another stimulus. As an example, in a study of 6- to 16-year-olds receiving venepuncture as part of their cancer care, Lioffi et al. (2009) found self-hypnosis superior for pain and anxiety relief as compared to control and attention conditions. A systematic review of the literature indicated that hypnosis is a viable intervention for procedural pain in paediatric oncology patients (Richardson et al., 2006). Further discussion on hypnosis can be found elsewhere in this volume (Lioffi et al., Chapter 54).

## Conclusion

Given the vast array of distraction techniques and study methodology reported, meta-analyses and review studies present an integrated overview of strengths and limitations in the literature, providing direction for future research. Koller and Goldman (2011) critically assessed studies evaluating distraction for children ranging from infant to young adults undergoing medical procedures and found support for such interventions, while also addressing important gaps in the literature. A systematic review of RCTs employing psychological interventions for children and adolescents during needle-related procedures found distraction to have one of the largest effect sizes in managing procedural pain and distress compared to control conditions (Uman et al., 2008). Specifically, studies sufficiently support the use of distraction for self-reported pain, a combination of distraction and suggestion for self-reported pain, a combination of nurse coaching and distraction for distress assessed behaviourally, and a combination of parent positioning (e.g. instructing the parent where to sit and how to hold the child) and distraction for distress using observer reports. A meta-analysis examining the mean effect sizes of distraction on children's distress behaviour and self-reported pain during medical procedures concluded that although distraction had a positive effect on children's distress behaviour, moderator variables influenced the effect of distraction on children's self-reported pain intensity. Specifically, the amount of explained variance significantly increased after controlling for child age and type of procedure, suggesting that other potential moderators may also influence this relation (Kleiber and Harper, 1999).

Although most reviews support distraction as an efficacious psychological intervention for paediatric procedural pain, study limitations and recommendations for future research are also presented. Many researchers fail to elaborate on the randomization procedure used or the nature of participant attrition, which limits the value of any significant results (Uman et al., 2006). Due to the minimal number of RCTs directly comparing distraction methods, it remains challenging to discern which interventions are most effective, particularly given their varying degrees of patient engagement. Moreover, many researchers also incorporate multiple distraction approaches in the intervention design, which makes it difficult to uniquely assess specific unique distraction techniques. Established methods must also be evaluated against novel interventions longitudinally, as the novel interventions may become less efficacious as child habituation gradually increases. In addition to accounting for a child's prior exposure to a particular form of distraction, future

research should also address patient preferences and other child-specific variables (e.g. temperament, past medical experience). Other areas of improvement include the incorporation of data to assess patients' and health care providers' personal experiences with distraction, recruiting larger sample sizes, examining both the short- and long-term effects of distraction, and using pain measures that have established validity. Finally, the paucity of objective measures of time spent actively engaged in distraction may also influence findings deemed significant (Koller and Goldman, 2011). Whereas distraction appears to be effective for pre-schoolers and school-age children, sufficient evidence to support the efficacy of distraction for procedural pain in infants has not been established (Cramer-Berness, 2007; Pillai Riddell et al., 2011).

In summary, there are ample data to support the general argument that distraction is an effective intervention for children's acute painful medical procedures (e.g. Kleiber and Harper, 1999). The literature supports a variety of distraction approaches used across routine (e.g. immunizations) and more invasive (e.g. burn debridement) paediatric procedures and with a range of patient populations. However, a closer inspection of the data reveals a complicated story with a number of variables (e.g. age, distraction technique, type of procedure) influencing the success of distraction for children's anxiety and pain mitigation. Future studies in distraction for paediatric procedural pain might more closely identify the mechanism of action. For example, it remains unclear as to whether the induction of a positive mood, the involvement of multiple sensory modalities, or other aspects (e.g. developmentally appropriate technique, engagement in distraction, parental attention during distraction) is critical. In fact, data suggest that mood and attention each might influence pain, but these two avenues do so in different ways (Villemure and Bushnell, 2002). In addition, the literature remains largely equivocal about matching distraction to patient characteristics, which is becoming increasingly important as pressure mounts to provide tailored treatment (Department of Health and Human Services, n.d.). For example, a handful of studies a number of years ago explored matching distraction to avoidance, blunter, or repressor coping style, but the findings were inconsistent (e.g. Christiano and Russ, 1998; Fanurik et al., 1993; Smith et al., 1989). Other fine-grained studies might identify individual patient characteristics and preferences useful in determining not only whether distraction might be beneficial to the paediatric patient, but what type of distraction would be optimal.

### Case example

A case example allows an opportunity to exemplify some of the research recommendations. Taking an evidence-based practice in psychology perspective, it is important to use clinical skills to tailor the scientific findings to the patient's characteristics, culture, and preferences (American Psychological Association, 2005). In this example, 'Johnnie' is an 8-year-old who is returning for an oncology port-access procedure. The staff have noted in his medical chart that Johnnie is consistently distressed for these procedures (sensitization is not uncommon for repeated procedures; Katz et al., 1980), his parents are opposed to any pharmacological intervention, and Johnnie enjoys Anime comics and movies. Thus, topical anaesthetics are not employed to minimize pain, and the nurse has secured an age-appropriate Anime video

and several Anime comic books. The nurse begins playback of the movie and engages Johnnie in conversation about the film in advance of the medical procedure to decrease anticipatory anxiety (e.g. Cohen, 2008). Johnnie's parents join the conversation and further encourage distraction, which is expected (e.g. Cohen et al., 1997). Given that Johnnie has undergone numerous port-access procedures, information about the procedure is minimized (for a review, see Jaaniste et al., 2007). When Johnnie displays or reports distress or pain, the nurse and parents briefly and neutrally acknowledge it but immediately re-engage him in the movie; and when the port-access procedure is complete, the nurse will continue to employ distraction strategies in order to minimize post-procedure distress. Consistent with recommendations in the literature (Cohen et al., 2001), Johnnie's hopelessly low to moderate anxiety and pain ratings might be retained in his medical chart so that he might review them at his next port-access procedure in order to decrease potentially distorted anticipatory anxiety.

## CHAPTER 54

# Hypnosis and relaxation

Christina Liossi, Leora Kuttner,  
Chantal Wood, and Lonnie K. Zeltzer

### Introduction

Psychological approaches to symptom management are among the oldest and are an intrinsic part of medical practice in every culture. Suggestive therapy is probably the oldest of all therapeutic methods and hypnosis under various names has been used for as long as records have been kept. Despite the fact that research on clinical hypnosis with children is still in an early stage of development and the child hypnosis literature is predominantly composed of anecdotal case histories and uncontrolled research studies, one of the best-documented uses of hypnosis is in the treatment of paediatric pain where hypnosis has achieved status as an evidenced-based/empirically supported intervention. In this chapter, the current research literature and clinical practice regarding the use of hypnosis in paediatric pain management will be discussed. First hypnosis is defined and theoretical conceptualizations are briefly discussed. Second, our current understanding of the mechanisms of hypnotic analgesia is presented. Third the research evidence for the efficacy of hypnosis in the control of acute and chronic paediatric pain is reviewed; in both sections relevant clinical techniques are discussed. Following, a description and discussion of different relaxation techniques and the evidence for their efficacy in acute and chronic pain management is presented. The chapter concludes with an attempt to summarize and evaluate the existing literature and make suggestions for future studies and clinical practice.

### Hypnosis

Hypnosis is a psychological state of heightened awareness and focused attention, in which critical faculties are reduced and susceptibility and receptiveness to ideas is greatly enhanced. Hypnotic induction procedures usually consist of 'an extended initial suggestion for using one's imagination' (Green et al., 2005, p. 262), or an invitation to focus one's attention. Hypnotic inductions traditionally involve suggestions to relax, although relaxation is not necessary for hypnosis, particularly with children who respond better to more active inductions. An induction can be quite brief or longer, depending upon the hypnotic subject's responsiveness and the clinician's preferences. During hypnosis the health care professional makes suggestions for changes in subjective experience, alterations in perception, sensation, emotion, thought or behaviour (Green et al., 2005; Liossi, 2011) (see Box 54.1 for examples of hypnotic

#### Box 54.1 Hypnotic induction and deepening techniques for young people

##### Favourite activity

Imagine building a Lego house at home; just let yourself feel that way now.

##### Arm levitation

Pay special attention to your hand and arm. Something interesting and strange is going to happen to them ... you become aware of how warm or cold your arm is, of little muscles in your hand and arm that twitch ever so slightly ... and now perhaps you would like to imagine ... that I am fastening a string around your wrist ... fastened to the other end of the string ... over there on the ground ... lies a balloon that is not yet blown up ... what colour is it? ... that's right it is bright yellow ... now the balloon is being filled with helium ... you can see the balloon lift off the ground and rise, rise higher and higher ... the string around your wrist becomes taut ... watch what happens to the arm ... yes, it is pulling the hand and arm up ...

##### Ascending cloud

You are relaxing on a warm sunny day, looking at a clear blue sky ... you see a fluffy white cloud floating gently down towards you ... Hop on the cloud ... the cloud starts going up again ... you feel yourself relaxing and drifting deeper and deeper into tranquillity as you remain immersed in the cloud ... that goes higher and higher ... you float at a comfortable height.

inductions and supplementary online materials for video clips). Hypnosis is a natural state of aroused, attentive focal concentration coupled with relative suspension of peripheral awareness. Because hypnotic capacity is a normal and widely distributed trait, and because entry into hypnotic states occurs spontaneously, hypnotic phenomena occur frequently. Even therapists who make no formal use of hypnosis can enhance their effectiveness by learning to recognize and take advantage of hypnotic mental states.

Children have blurred boundaries between fantasy and reality, a factor that makes them ideal candidates for hypnotic interventions. They are open to new experiences, find hypnosis interesting and

have few if any preconceived ideas and reservations about hypnosis. Unlike adults, children usually move and talk during hypnosis without this meaning that they are disengaging from the intervention. Young patients can also easily be taught and learn self-hypnosis, which is the act of administering hypnotic procedures on one's own (Gardner and Olness, 1981). As the therapist guides the individual to experience the hypnotic suggestions as they develop, this promotes a feeling of being active and creative in the therapeutic process and facilitates a kind of 'playful' engagement between the therapist and the child (Kuttner, 1988; Liossi and Mystakidou, 1996) which is one of the cornerstones of pain management. This engagement, while challenging, is a necessary first step in building a therapeutic alliance in which the patient, family, and therapist work together to achieve a common goal.

In paediatric practice, working with children and adolescents means working with parents from the very beginning, when evaluating the problem and throughout the treatment process. Guiding the parents to focus on and actively facilitate the use of coping strategies such as hypnosis by the young patient helps the patient and family gain a sense of control over the pain. Successful parenting strategies often strike a balance between protection and acting as a 'life coach'. In many cases parents can serve as 'life coaches' and guide, especially younger patients, to use hypnosis (see supplementary online materials for video clips).

Theoretical conceptualizations of hypnosis can be loosely classified under state and non-state, intrapersonal and interpersonal, or single and multifactor theories (Yapko, 2003) (it is beyond the scope of this chapter to discuss the merits and controversies surrounding each theory, see Kallio and Revonsuo (2003), for a review). State, intrapersonal, and single theorists maintain that hypnosis represents a cognitive process distinct from normal day-to-day cognitive processes and conceptualize it as a trance state or an altered state of consciousness, i.e. the neodissociative (Hilgard and Hilgard, 1994) and 'dissociative control' views (Bowers, 1992). The neodissociative model regards hypnosis as a state in which one or more forms of consciousness is split off from the rest of mental processing. Bowers and his colleagues maintained that subsystems of control in the brain can be activated directly rather than through higher level executive control. In other words, the strategies subjects used to reduce pain were evoked automatically without any type of conscious strategy (Bowers, 1990, 1992).

The non-state, interpersonal, and multifactor theorists, also known as sociocognitive theorists, suggest a social-psychological explanation of hypnosis. These theorists maintain that there is nothing unique about hypnosis and argue that most of the hypnotic phenomena can occur without a hypnotic induction or trance, that neither hypnotic induction nor the existence of an altered state of consciousness are necessary for hypnotic responding, including responses to suggestions for pain relief (Chaves, 1993). Hypnotic analgesia is thought to reduce pain instead through cognitive-behavioural mechanisms, in which changes in cognitions are thought to alter the affective states associated with pain (Chaves, 1993). The model suggests that the operative variables in hypnosis include contextual cues in the social environment, patient and subject expectancies, demand characteristics of the setting or situation, and role enactment (Kirsch and Lynn, 1995; Patterson and Jensen, 2003; Spanos and Chaves, 1989). The intrapersonal theories of hypnosis emphasize the subjective and inner states of the hypnotized person, whereas the interpersonal models attach more importance to

the social context or relational aspects of the hypnotic interaction (Yapko, 2003).

Even though debates and controversies in the field of hypnosis have been dominated by the opposition between 'state' and 'non-state' theories, these two theoretical approaches are not mutually exclusive, have several lines of convergence, and none of these can satisfactorily explain all the phenomena associated with hypnosis. More recent theorists have suggested that attempting to explain the effects of hypnosis solely in terms of one school of thought presents distinctions that are too arbitrary and the different formulations have certainly broadened our understanding of the subject and informed clinical practice (Kihlstrom, 1992; Kirsch and Lynn, 1995; Lynn et al., 2000).

Although hypnotic analgesia is among the oldest treatments for pain (Elliotson, 1843), interest in its use seems to wax and wane. Currently, interest in hypnotic treatments for acute and chronic pain in general and paediatric pain in particular appears to be on the rise, possibly due to: (1) confirmation from adult imaging studies that chronic pain is largely influenced by, and may at times be primarily the result of, supraspinal neurophysiological processes (Jensen, 2009); (2) evidence that hypnosis has observable influences on the neurophysiological processes associated with pain (Jensen, 2009); (3) empirical evidence that hypnotic analgesia is effective for acute pain particularly procedure related and promising results from the use of hypnosis in chronic pain management.

## Mechanisms of hypnotic analgesia

Early research on the neurophysiological underpinnings of pain focused on peripheral activity emanating from the site of injury. With the introduction of the gate control theory (Melzack and Wall, 1965) the focus shifted to the spinal cord and with recent improvements in imaging technology, there has been a dramatic increase in the study of the central neurophysiological correlates of pain. Now more than ever, we understand how multiple integrated pain networks work together to contribute to the global experience of pain and that the neurophysiological processes that underlie the experience of pain have peripheral, spinal, and supraspinal nervous system components (for more detail see Apkarian et al., 2005; Byers and Bonica, 2001; Craig, 2003; Terman and Bonica, 2001; Rainville, 2002).

Current evidence shows that hypnotic suggestions of analgesia may modulate pain processing at multiple levels and sites within the central nervous system. At the *peripheral* level, hypnosis may modulate nociceptive input by downregulating A delta and C fibres stimulation (Benhaïem et al., 2001) and reducing sympathetic arousal (De Benedittis et al., 1994). At a *spinal* level, sensory analgesia during hypnosis has been shown to be linearly related to a reduction of the nociceptive flexion (RIII) reflex, a polysynaptic spinal reflex that is not subject to voluntary control (Kiernan et al., 1995). Using a methodology similar to that of Kiernan et al. (1995), Danziger and colleagues (Danziger et al., 1998) later found two patterns of RIII reflex associated with hypnotic analgesia in 18 individuals with high levels of hypnotizability: 11 of their study participants showed clear inhibition and seven showed facilitation of the spinal nociceptive reflex following hypnotic analgesia suggestions. Although the reasons for the differences in response are not easily explained, they do indicate that highly suggestible individuals can show changes in spinal nociceptive reflex when given hypnotic analgesia suggestions.

A number of supraspinal sites have been shown to be involved in the perception of pain, but the areas that have been identified, most consistently, across different imaging studies are the thalamus, the primary and secondary somatosensory cortex (S1 and S2), the anterior cingulate cortex (ACC), the insula, and the prefrontal cortex (see also Apkarian et al., 2005; DeLeo, 2006). At *supraspinal* cortical level, neuroimaging studies have shown that hypnosis has direct effects on many supraspinal sites involved in the experience of pain and that hypnotic suggestions of analgesia can modulate directly both sensory and affective dimensions of the pain perception. Derbyshire and colleagues, for example, have shown that suggestions for feeling pain in the hand in healthy, pain-free individuals resulted in self-reports of pain and increased activity in the thalamus, ACC, insula, prefrontal, and parietal cortices (Derbyshire et al., 2004). The effects of suggestions on both pain intensity and cerebral activation were stronger when the suggestions followed a hypnotic induction than when participants were asked to simply ‘imagine’ pain without a hypnotic induction. In a follow-up study, Derbyshire and colleagues suggested to individuals with chronic pain that they would experience their clinical pain as being of ‘low’, ‘medium’, and ‘high’ intensity, both following and not following a hypnotic induction (Derbyshire et al., 2009). Suggestions for high pain resulted in increases in both pain and in cortical activity associated with the experience of pain, whereas suggestions for low pain resulted in decreases in pain and in cortical activity in these same areas. Similarly, to their earlier study (Derbyshire et al., 2004), the suggestions had larger effects following a hypnotic induction.

Hypnotic modulation of pain dramatically alters the cortical pain matrix. The hypnotic modulation of pain intensity produces changes in pain related activity mainly in the S1, while modulation of pain unpleasantness induces changes mainly in the ACC, with the anterior (mid) cingulate cortex possibly modulating both sensory and affect components of pain (Faymonville et al., 2000; Peyron et al., 2000). Two eloquent experimental studies have demonstrated that hypnotic suggestions can selectively alter the pain experience and have ‘targeted’ effects on different cortical areas. In the first, Rainville and colleagues demonstrated that hypnotic suggestions for decreased and increased pain unpleasantness succeeded in reducing and increasing ratings of pain unpleasantness, respectively, but did not affect ratings of pain intensity (Rainville et al., 1997). Consistent with the self-report findings, these same hypnotic suggestions resulted in decreases and increases in activity in the ACC only. In a follow-up study, Hofbauer and colleagues showed that hypnotic modulation of the intensity of the pain sensation led to significant changes in pain evoked activity within S1 (and a trend in S2), but not in the ACC (Hofbauer et al., 2001). This double dissociation of cortical modulation indicates a relative specialization of the sensory and the classical limbic cortical areas in the processing and modulation of the sensory and affective dimensions of pain.

However, it has to be noted that these are adult studies and differences exist between adult and child brains. Brain structural and functional development, throughout childhood and into adulthood, underlies the maturation of increasingly sophisticated cognitive abilities and a shift with age from the recruitment of ‘bottom-up’ processing regions towards ‘top-down’ fronto-cortical and fronto-subcortical connections, suggesting progressive functional integration and segregation with age leading to a more mature, and controlled cognition (Rubia, 2012). A review (Rubia, 2012) of the functional magnetic resonance imaging (fMRI) literature on brain

function development of typically late developing functions of cognitive and motivation control, timing and attention as well as of resting state neural networks shows that between childhood and adulthood, concurrent with cognitive maturation, there is progressively increased functional activation in task-relevant lateral and medial frontal, striatal, and parieto-temporal brain regions that mediate these higher level control functions. This is accompanied by progressively stronger functional inter-regional connectivity within task-relevant fronto-striatal and fronto-parieto-temporal networks. Negative age associations are observed in earlier developing posterior and limbic regions. This developmental maturation trajectory could explain the development of increasing pain coping abilities in adolescents vs. in children.

High-level attentional and cognitive control processes rely on the integrity of, and dynamic interactions between, core neurocognitive networks. The right fronto-insular cortex (rFIC) is a critical component of a salience network (SN) that mediates interactions between large-scale brain networks involved in externally oriented attention (central executive network (CEN)) and internally oriented cognition (default mode network (DMN)). Structural and functional maturation of the right fronto-insular cortex pathways is a critical component of the process by which human brain networks mature during development to support complex, flexible cognitive processes in adulthood (Uddin et al., 2011). Furthermore, neurons within the lateral ventromedial thalamic nucleus (VMI) convey selectively nociceptive information from all parts of the body. VMI neurons driven by ‘whole-body’ nociceptive receptive fields project to the rostral part of the layer I of the dorsolateral frontal cortex. The VMI comprises a homogeneous, organized subset of thalamic neurons that allow any signals of pain to modify cortical activity in a widespread manner, by interacting with the entire layer I of the dorsolateral neocortex (Monconduit and Villanueva, 2005).

Overall, in brain development a general pattern of functional and structural increases in connectivity and integrative processing, and a changing balance between limbic/subcortical and frontal lobe functions that extend well into young adulthood exist. Given the evidence for experience-driven structural plasticity (Markham and Greenough, 2004) an exciting yet untested hypothesis is that regular use of hypnosis by young people enhances this top-down pathway and strengthens cortical connectivity. Quantification of intervention-related changes in brain structure and function may provide further useful information about the neural mechanisms underlying the hypnotically induced pain reduction in young people with pain and also knowing which neural systems have been modified may, in turn, provide additional insights relevant for fine-tuning of the initial therapeutic strategy.

## Hypnosis in acute pain management

There is strong support for the efficacy of hypnosis in procedure-related pain management and hypnosis has achieved status as an empirically validated, possibly efficacious intervention in the management of paediatric procedure-related pain (Lioffi, 1999) according to the criteria devised by the American Psychological Association to judge the efficacy of psychological interventions (Chambless and Hollon, 1998). All studies conducted to date (Butler et al., 2005; Hawkins et al., 1998; Hilgard and LeBaron, 1982; Katz et al., 1987; Kellerman et al., 1983; Kuttner, 1988; Lioffi and Hatira, 1999, 2003; Lioffi et al., 2006, 2009; Smith et al., 1996; Wall and Womack, 1989;

Zeltzer and LeBaron, 1982) found hypnosis effective in reducing the pain and anxiety of young patients during painful medical procedures such as lumbar punctures, bone marrow aspirations, venepunctures and voiding cystourethrograms. A meta-analysis concluded that hypnosis is the most promising psychological intervention for needle procedures (Uman et al., 2006). Limited support is available in the paediatric literature that hypnosis significantly lowers postoperative pain and anxiety ratings and contributes to shorter hospital stays (Lambert, 1996).

In the most recent prospective controlled trial, the efficacy of self-hypnosis in combination with a local anaesthetic (EMLA®) was compared with EMLA® in the relief of venepuncture-induced pain and anxiety in 45 paediatric cancer outpatients (age 6–16 years; Liozzi et al., 2009). Patients were randomized to one of three groups: local anaesthetic, local anaesthetic plus hypnosis, and local anaesthetic plus attention. Results confirmed that patients in the local anaesthetic plus hypnosis group reported less anticipatory anxiety, and less procedure-related pain and anxiety, and were rated as demonstrating less behavioural distress during the procedure than patients in the other two groups. The therapeutic benefit of the brief hypnotic intervention was maintained in the follow-up. Moreover, parents whose children were randomized to the EMLA plus hypnosis condition experienced less anxiety during their child's procedure than parents whose children had been randomized to the other two conditions. These findings are particularly important in that this study was a randomized, controlled trial conducted in a naturalistic medical setting.

Different hypnotic analgesic techniques can be used for acute pain management including direct suggestions such as pain displacement, symptom substitution, time distortion, topical anaesthesia, glove anaesthesia (see supplementary online materials for video clip), dissociation (see Liozzi, 2002), and indirect suggestions such as therapeutic stories and metaphors. Direct and indirect suggestions have been found to be equally effective (Liozzi and Hatira, 2003) (Box 54.2 provides examples of hypnotic techniques). Four out of five studies (Hilgard and LeBaron, 1982; Liozzi and Hatira, 2003; Liozzi et al., 2006, 2009; Wall and Womack, 1989) that have examined the relationship between the child's hypnotizability and pain relief during painful medical procedures reported a significant positive relationship between hypnotizability and clinical benefit following hypnosis treatment although the majority of children received some benefit from the intervention. In all randomized trials conducted so far, the role of the parents was critical and only their direct involvement in the intervention secured the maintenance of the therapeutic effect in when children were using self-hypnosis (Liozzi et al., 2006, 2009).

## Hypnosis in chronic pain management

Well-designed clinical trials and accumulated clinical experience (Banez, 2008; Galili et al., 2009) support the view that hypnosis is the most efficacious treatment for chronic abdominal pain improving pain and disability outcomes and needs to be an integral part of the biobehavioural approach to management. Chronic abdominal pain (CAP) is long lasting, intermittent, or constant pain affecting 15% to 30% of children ages 4 to 18 and presents a diagnostic and treatment challenge to the physician. Most children with this disorder are found to have no specific organic aetiology (functional abdominal pain), the predictive value of diagnostic tests is questionable, and studies of the treatment of chronic abdominal pain show inconclusive

### Box 54.2 Hypnotic analgesic techniques for acute pain management

#### Switchbox

The therapist explains to the child the idea that pain is transmitted by nerves from various parts of the body to the brain, which then sends a 'pain message' back to the body (coloured drawings can be used to facilitate this explanation). The patient is asked to choose a switch that can turn off or modulate incoming nerve signals situated whenever they want (e.g. in the brain or near the site of pain). Patients are asked to practise turning the switches progressively down for defined periods of time starting with 10 to 15 secs and working up to longer periods.

#### Topical anaesthesia

Imagine painting numbing medicine or cream onto that part of your body and make it go deep into your skin to protect you ...

#### Moving pain away from the self

Imagine for a while that that arm (or other body part) doesn't belong to you, isn't part of you ... see it just floating out there by itself, taking all the pain away ...

#### Directing attention to pain itself

Imagine that you have come from another planet far deep in the Universe where there is no pain ... you have never experienced pain before ... notice the discomfort very carefully ... be curious about what sensations you have ... how does it make you feel ...

evidence regarding diet regimens as well as medical and surgical treatments (Di Lorenzo et al., 2005).

In a randomized controlled trial of 53 paediatric patients Vlieger and colleagues (Vlieger et al., 2007) compared clinical effectiveness of hypnotherapy (HT) with standard medical therapy (SMT) in children with functional abdominal pain (FAP) or irritable bowel syndrome (IBS). Patients were randomized to either HT or SMT. Hypnotherapy consisted of six sessions over a 3-month period. Patients in the SMT group received standard medical care and six sessions of supportive therapy. After 3 months of therapy, 59% of the patients in the HT group were in clinical remission with another 26% significantly improved. In the control group, receiving standard medical treatment (SMT), only 12% was in remission and 32% improved. One year after treatment, 85% of the patients treated with HT were asymptomatic versus 25% of the children who received SMT. Clinical remission was defined as greater than 80% improvement in pain scores compared with baseline.

In a follow-up study, the same investigators (Vlieger et al., 2012) explored the long-term effects of HT versus standard medical treatment plus supportive therapy (SMT). All 52 participants of their previous randomized controlled trial (RCT) were invited to complete a standardized abdominal pain diary, on which pain frequency and pain intensity were scored. All 27 HT patients and 22 out of 25 SMT patients participated in this study. After a mean duration of 4.8 years' follow-up, HT was still highly superior to conventional therapy with 68 versus 20% of the patients in remission after treatment. Also, somatization scores were lower in the HT group. However, no differences were found in quality of life, doctors' visits, and missed days of school or work between the two groups.

Vlieger and colleagues further concluded that the clinical success achieved with HT in their studies cannot be explained by improvement in rectal sensitivity (Vlieger et al., 2010). In one study they randomized 46 patients with FAP ( $n = 28$ ) or IBS ( $n = 18$ ) to either 12 weeks of SMT or HT. To assess rectal sensitivity, a pressure-controlled intermittent distension protocol (barostat) was performed before and after the therapy. Interestingly, no relationship was established between treatment success and rectal pain thresholds. Rectal sensitivity scores at baseline were not correlated with intensity, frequency, or duration of abdominal pain.

The multifaceted and complex nature of chronic pain requires elaborate and comprehensive hypnotic interventions delivered in a number of sessions and regular and consistent use of self-hypnosis by the patient (Wood and Bioy, 2008). Especially, when considering biopsychosocial and neuropsychological models of pain, using a combination of pain-specific and non-pain-related suggestions may be particularly effective because these suggestions can target not only pain itself, but emotional (e.g. suggestions for improved mood), cognitive (e.g. suggestions for increased self-efficacy), and behavioural (e.g. suggestions for improved sleep) factors that play an important role in the pain experience (Dillworth and Jensen, 2010). Details of the interventions will differ depending on the exact nature of the problem, the purposes of the clinical endeavour, the goals of the health care professional, and the abilities and preferences of the young patient and their family (Liossi, 2011). Box 54.3 shows an example of a hypnotic session for chronic pain management and the case example illustrates a hypnosis based therapeutic approach across time.

Hypnotic strategies and techniques for managing chronic pain, among others, include: creating anaesthesia or analgesia, a decrease in pain, an increase in comfort and relaxation, changes in sensations from unpleasant (burning) to more pleasant (warm) ones, feeling less bothered by sensations, or changes in the meaning of pain, unconscious exploration to enhance insight or resolve conflict, cognitive-perceptual alteration of pain (and pain behaviour), and decreasing awareness of pain (distraction techniques). Other useful hypnotic approaches to pain management include self-suggestions for relaxation and a sense of global calmness, ego strengthening, being in a 'special place' (that is, a place that is beautiful, safe, relaxing, and calming to the young patient; see supplementary online material for video clip), decreased tension and emotional suffering, maintaining an appropriate level of activity, focusing on life goals other than just pain reduction, increasing participation in distracting and healthy activities, appropriate activity pacing and Rossi's (Rossi et al., 2010) mind-body healing approach. In this latter approach, hypnotic suggestions can be given during the treatment session for the patient to regress and access past learning, memory, and experience and use them as therapeutic resources for pain management.

However, it needs to be acknowledged that chronic pain in children is a multifactorial condition not easily addressed by one technique only. Multidisciplinary management is required and hypnosis should be part of a cognitive-behavioural treatment framework (see also Zeltzer and Blackett-Schlank, 2005, Kuttner, 2010).

#### **Box 54.3** Example of a hypnotic treatment session for chronic pain management

##### **Induction and deepening suggestions**

Get ready to go aboard a submarine for an extraordinary journey under the sea! Dive deeper and deeper until the water is dark blue ... look through your periscope, peek under flaps, put your scuba diving equipment on ... open an airlock ... and dive into the ocean ...

##### **Analgesic suggestions**

The water temperature is pleasant ... your body relaxes ... you float happily ... any discomfort that you may be experiencing is leaving your body ... dissolving into the water ... meet ocean animals ... look at the bottom of the sea ...

Imagine going back in time ... to a time some time ago, before any pain or discomfort, when you were full of energy and had a sense of complete well-being ... when you come back to the here and now you will feel again the same sense of well-being ...

Now see the pain ... what shape is it? ... see its colour? ... feel its texture? ... now change the shape, colour and texture ...

##### **Ego-strengthening**

You are going to feel physically stronger and fitter in every way ... you will be surprised how enthusiastically you find yourself working on your physio exercises ... you will notice feeling more alert ... more wide awake ... every day ... you'll be more curious and interested in school and extracurricular activities ... in your friends and family ... in whatever is going on around you ... so that your mind will become completely distracted away from yourself and your difficulties ... you will be able to think more clearly ... and notice how you become emotionally calmer ... every day ... you will feel more and more independent ... every day ... you will feel a greater feeling of well-being ...

##### **Post-hypnotic suggestion**

From now, each and every time you feel these sensations (pain) in your muscles and bones you will immediately take in a deep breath, and as you breathe out your whole body will relax ...

##### **Termination**

Now I would like you to count backwards from 5 to 1 ... 1 you are feeling refreshed and alert and ready to continue with whatever you were doing before...

### Case example

AB, a 17-year-old athlete sustained a severe injury to her shoulder in an unexpected fall. She had several months of physiotherapy with little progress and surgery was recommended to stabilize her shoulder joint. Following surgery she developed a frozen shoulder complication resulting in a severely restricted range of motion and exquisitely tender shoulder capsule. She continued with physiotherapy but now had significant limitations in her capacity to care for herself.

Daily pain became part of her life. As a result of continuous pain, she walked protecting her shoulder from accidental bumps, avoiding crowded places and became increasingly anxious about incurring further pain. After almost 2 years of living with daily pain, physical limitations, and increasing despair, she was referred for pain management.

She presented as an organized, motivated teen, who tearfully stated that pain was a steady part of her life. Despite pain and mobility restrictions, she successfully passed her exams. She complained of continual exhaustion and difficulty sleeping. She experienced secondary neck and back pain and presented as emotionally vulnerable and mildly depressed.

### Treatment

Combined with ongoing physiotherapy and pharmacotherapy, hypnosis, and relaxation were used to repattern her brain-body connection so that she could learn to:

- ♦ Successfully release tension and relax more effectively.
- ♦ Develop an awareness of well-being.
- ♦ Experience her body as capable of healing.
- ♦ Decrease intensity and areas of pain.
- ♦ Sleep and wake refreshed.
- ♦ Take accurate physical inventory.

*First hypnosis session—therapeutic focus:* use breath to release learned physical constrictions.

Using her breath as induction, AB was coached into slow rhythmic diaphragmatic breathing to track sensory changes: ‘Notice how easily your chest opens and how this invites more comfort into ... and throughout your body ...’ ‘You can do this effortlessly and experience the softening throughout your body’ (this a more effective way of saying, ‘don’t try so hard!’).

AB reported: ‘experiencing a huge weight lifted from me. I feel free and so relaxed. For the first time in many months, or maybe years, I’m breathing properly. I hadn’t realized I wasn’t breathing properly!’.

She undertook to practise this daily

*Second hypnosis session—therapeutic focus:* targeting release of her secondary neck and back pain.

Using a helium balloon as hypnotic metaphor, AB was invited to focus her attention and experience her head ‘floating freely and light, so that her neck was freed of any needless holding, and her shoulders could hang-down like an ordinary well-functioning coat-hanger’

AB reported: becoming more aware of her body and wondering if ‘this protection could be contributing to my pain!’. This focus helped her stop guarding her arm. *Third hypnosis session—therapeutic focus:* recreating a stable reliable sleep pattern AB closed her eyes and focused on experiencing the physiological process of falling asleep. She was given the suggestion that she could rely on this occurring each night and her body would restore itself while her mind drifted easily into dreams. In the morning she would wake refreshed, getting out of bed with a sense of purpose knowing what needs to be done and doing it comfortably.

AB reported improved sleep patterns and as a result, increased energy.

*Forth hypnosis session—therapeutic focus:* empowering her to assess her physical status. Using the ‘body scan’ hypnotic technique, AB was invited to shrink herself and travel inside her body checking out her shoulder, neck, and back and take an inventory and adjust herself for comfort. At termination AB was still using this technique. Her pain has diminished over time, range of motion greatly increased, and her mood improved.

## Relaxation

McCaffery and Beebe (1994, p. 188) define relaxation as ‘a state of relative freedom from both anxiety and skeletal muscle tension, a quieting or calming of the mind and muscles’. This situation is characterized by decreased intake of oxygen, decreased muscle tone, lower heart and respiratory rates, normal blood pressure, decreased skin resistance and intense, slow alpha-waves in the brain (Bulechek, 1992; McCaffery and Beebe, 1994; Watt-Watson, 1992).

There are different types of relaxation including tension-release (Jacobson, 1938), autogenic (Schultz and Luthe, 1969) and meditation (Perez-De-Albeniz and Holmes, 2000). Tension-release

relaxation involves slowly tensing and then releasing each muscle group individually, starting either with the muscles in the toes and finishing with those in the head or visa verse. In autogenic training both visual imagery and body awareness are used to move a person into a deep state of relaxation. The person imagines a peaceful place and then focuses on different physical sensations, moving from the feet to the head. For example, one might focus on warmth and heaviness in the limbs, easy, natural breathing, or a calm heartbeat. Box 54.4 describes a simple autogenic relaxation exercise. The two most popular forms of meditation include transcendental meditation where the patient repeats a mantra, i.e. a single

**Box 54.4** Autogenic relaxation technique

1. Choose a quiet place where you won't be interrupted.
2. Before you start, do a few gentle stretching exercises to relieve muscular tension.
3. Make yourself comfortable, either sitting or lying down.
4. Start to breathe slowly and deeply, in a calm and effortless way.
5. Focus on each part of your body, starting with your feet and working your way up to your face and head.
6. As you focus on each area, think of warmth, heaviness (or lightness) and relaxation.
7. Imagine any distracting thoughts floating away like the bubbles in a fizzy drink.
8. Stay like this for about 20 min, then take some deep breaths and open your eyes, but stay sitting or lying for a few moments before you get up.

word or phrase and mindfulness meditation. Mindfulness refers to a particular way of paying attention, that is purposefully paying attention to moment-to-moment experience in a non-judgemental and accepting manner (Kabat-Zinn, 1996). As yet, research within child and adolescent populations is in its initial stages, although preliminary results of a clinical trial have evidenced the ability of children and adolescents with chronic pain to engage with the mindfulness material and adhere to regular home practice of the techniques and apply them to presenting problems (Golianu and Waelde, 2012). After successful implementation in adult health practice, mindfulness meditation groups are beginning to gain traction in paediatric settings.

Although, approximately 43% to 58% of paediatric hospitals in the US use relaxation across a variety of acute pain situations (O'Byrne et al., 1997) doubt exists in the paediatric pain literature regarding the efficacy of relaxation as an analgesic in acute pain management. Similarly relaxation in chronic pain is usually part of a multicomponent cognitive-behavioural intervention, and can be used as a first step to establish changes in muscle tension release and some personal competency.

There is a large body of related therapies with conceptual and practical similarities that are grouped together under the term 'relaxation therapies' (NIH Technology Assessment Panel, 1996) and a corresponding large body of literature examining the effectiveness of these treatments in children with headache. Overall, even though most of these studies include children with poorly defined or several different types of headaches, this literature indicates that these techniques are effective. Two meta-analyses (Palermo et al., 2010; Trautmann et al., 2006) have provided evidence for the efficacy of relaxation training as an important treatment option for recurrent headache in childhood and adolescence although conflicting evidence exists about the effectiveness of relaxation therapy when compared with no treatment or other treatments in children with tension-type headaches (Verhagen et al., 2005). Meta-analytic findings have demonstrated a large positive effect of relaxation on pain reduction at immediate post-treatment and follow-up in youth with

headache, whereas small and non-significant effects were found for improvements in disability and emotional functioning. Long-term improvements over more than 3 years after treatment with relaxation, for tension-type as well as migraine headaches, have also been shown. Recently, applied relaxation has been presented via the Internet to children and adolescents with recurrent headache with positive effects recorded in headache frequency and duration and pain catastrophizing (Trautmann and Kroner-Herwig, 2010).

The choice of relaxation technique depends on the pain problem, the patient's preferences and abilities, professional availability, and available time. Patterson (Patterson, 1992) points out that progressive muscle relaxation generally requires lengthy and frequent training before the technique is sufficiently mastered. Certain patient populations, burned children for example, are often too exhausted and ill to invest the time or have the discipline required to learn these techniques. Taal (1998) expresses further objections to this technique because the muscles must be tensed before they can be relaxed. Muscle tension in burned parts of the body can further increase pain during wound care. In other words, even a simple technique such as progressive muscle relaxation can be inappropriate for specific pain conditions. More benefit for these patients can be expected from the use of alternative techniques such as meditation, hypnosis, or autogenic relaxation (Patterson, 1992; Taal, 1998).

## Conclusion

Hypnosis and relaxation are useful therapeutic techniques for the management of acute and chronic paediatric pain, although evidence for their efficacy varies depending on the type of pain. Hypnosis is an evidence-based intervention for procedure-related pain, and appears promising in the management of chronic pain with large, well-designed studies with robust methodologies, adopting standardized formats for interventions, needed to develop a firm research evidence base. There is strong evidence that relaxation can reduce pain in children with headache both in the short and long term and some evidence that it can reduce pain outcomes in both acute and chronic non-headache pain, but in these cases relaxation is better utilized as a part of multicomponent intervention rather than a standalone treatment.

## CHAPTER 55

---

# New information and communication technologies for pain

Jennifer Stinson and Lindsay Jibb

### Summary

The rapid growth in the amount and availability of information and communication technology (ICT) in the last decade means that several new tools have become available to monitor and manage chronic pain. These tools include the Internet (and associated social support networks), mobile phones, and telemedicine and they are being used to enable self-management by people suffering from persistent pain. The benefits of ICT-based pain therapies are many and include improved treatment accessibility and satisfaction, as well as potential decreases in therapy cost. ICT therapies for people in pain represent exciting treatment possibilities. Future, rigorous research into the design and effectiveness of these therapies will shed more light on how ICT might improve the quality of life for people with chronic pain.

### Introduction

Over the past decade there has been tremendous growth in the development and evaluation of ICT to deliver health care interventions including those for the treatment of chronic pain. Results from a 2010 telephone survey of 3001 American adults showed that 80% of Internet users accessed health information online and 14% accessed information specific to managing chronic pain (Fox, 2011). From a public health perspective, there is great potential for self-administered treatments to improve the health of individuals who suffer from chronic pain but are unable to access services. ICT-based programmes offer an innovative approach to improve the availability, accessibility, and acceptability of these programmes. This chapter will review ICT for pain by: defining chronic pain self-management, discussing barriers to the provision of pain self-management and psycho-educational interventions, and discussing methods by which ICT can overcome these barriers. The theories, processes, and content elements of ICT-based chronic pain programmes are defined and described. The evidence, where available, from treatment intervention trials and the advantages and disadvantages of telehealth, internet-based programmes, and mobile-health (m-health) or

Smartphone applications (apps) for the management of chronic pain are reviewed. Future directions for theory, research, and clinical practice are also described.

### Chronic pain self-management

Chronic pain is common in adults (Johannes et al., 2010) as well as children and adolescents (King et al., 2011) and can negatively impact all aspects of life including physical, emotional, social, and role functioning (Law et al., 2012; Palermo, 2000; Reid et al., 2011). Chronic pain may include varying amounts of disability and may be independent of the amount of tissue damage and perceived severity of injury (Huguet and Miro, 2008; Melzack and Wall 1965). In the likely absence of a cure or total pain relief, the prevention of pain-related disability and the improvement of quality of life through better chronic pain self-management are critical (Ritterband et al., 2003). Self-management can be defined as 'the individual's ability to manage the symptoms, treatment, physical, and psychological consequences and lifestyle changes inherent in living with a chronic illness' (Barlow et al., 2002).

Self-management interventions that provide individuals with knowledge about pain, strategies to manage pain (cognitive-behavioural therapies or CBT), and social support are needed to promote optimal health outcomes. Studies in adult chronic illnesses (Foster et al., 2007; Lorig and Holman, 1993; Smith et al., 2005) have shown that comprehensive interactive face-to-face psycho-educational interventions lead to symptom reduction and improved quality of life compared with care that is strictly medication focused. The proposed mechanism of effect for this phenomenon is presumed to be enhanced self-efficacy (i.e. belief in one's ability to successfully perform a behaviour) and empowerment over disease and symptom management (Marks et al., 2005a, 2005b). For example, Lefort and colleagues (1998) found that a 12-h community-based, chronic pain psycho-educational programme led to significant short-term improvements in pain, independence, vitality, aspects of role functioning, life satisfaction,

self-efficacy and resourcefulness compared to a wait-list control group in adults with chronic pain.

Variations in pain-related disability exist in young people and adults with chronic pain. However, the majority of the variance is related to several physical, psychological, and social variables (Bargiel-Matusiewicz and Krzyszkowska, 2009; Lynch et al., 2007). Thus, intervening in the pain experiences of young people and adults with chronic pain requires a broad framework that comprehensively addresses the physical and psychosocial precipitants, as well as modifiers and consequences, of chronic pain (Rapoff and Lindsley, 2000). The most successful interventions in improving pain and associated impairments in adults with chronic health conditions (including pain) are based on CBT (LeFort et al., 1998). CBT incorporate normalization of the patient's experience through education about the condition and its impact, training in specific strategies, including managing disease-related and other stressors, and guidance on developing and implementing a long-term plan for self-managing the condition (Palermo et al., 2010).

## **Barriers to the provision of pain psychosocial interventions**

There is a solid empirical foundation supporting CBT interventions to equip individuals with the necessary coping skills to reduce chronic pain and pain-related disability (Barlow et al., 1999; Jensen, 2010; Lineker et al., 1996; Stinson et al., 2012). Historically, barriers to accessing comprehensive chronic pain-specific education and cognitive behavioural coping skills training have included: (1) limited access to services in many geographic areas (including rural and remote regions), (2) language barriers (programs offered only in English), (3) and long-wait times (Elgar and McGrath et al., 2003; Peng et al., 2006; Stinson et al., 2008; Stinson et al., 2010); (4) limited availability of trained professionals such as psychologists, particularly in non-urban centres; (5) time restrictions limiting the amount of content reviewed during regular chronic pain clinic or primary care visits; and (6) additional costs (direct and indirect) including costs of CBT and time off work and/or school associated with these therapies (Barlow and Ellard, 2006; Barlow et al., 1999; Elgar and McGrath, 2003; Lineker et al., 1996; Stinson et al., 2012).

## **New technologies as an intervention medium to overcome barriers to pain care**

With emerging ICT (e.g. telehealth, Internet, smartphone apps), new media for the delivery of health interventions are now available (Ritterband et al., 2003). For example, the Internet has emerged as one of the top health information resources and modes of social communication, especially for youths and young adults, and continues to be increasingly integrated into the provision of health care services (Drotar et al., 2006; Gray et al., 2005; Griffiths et al., 2006). In developed countries, the vast majority of people have Internet access at home, work, school, or through the use of mobile technology (Fox, 2011; Klasnja and Pratt, 2012). ICT provides patients, families, and health care professionals with unparalleled opportunities to: (1) learn, inform, and communicate with one another; (2) receive meaningful social support; (3) fulfil the rising demand for expedient access to evidence-based health information; and (4) achieve greater involvement in health care decision-making

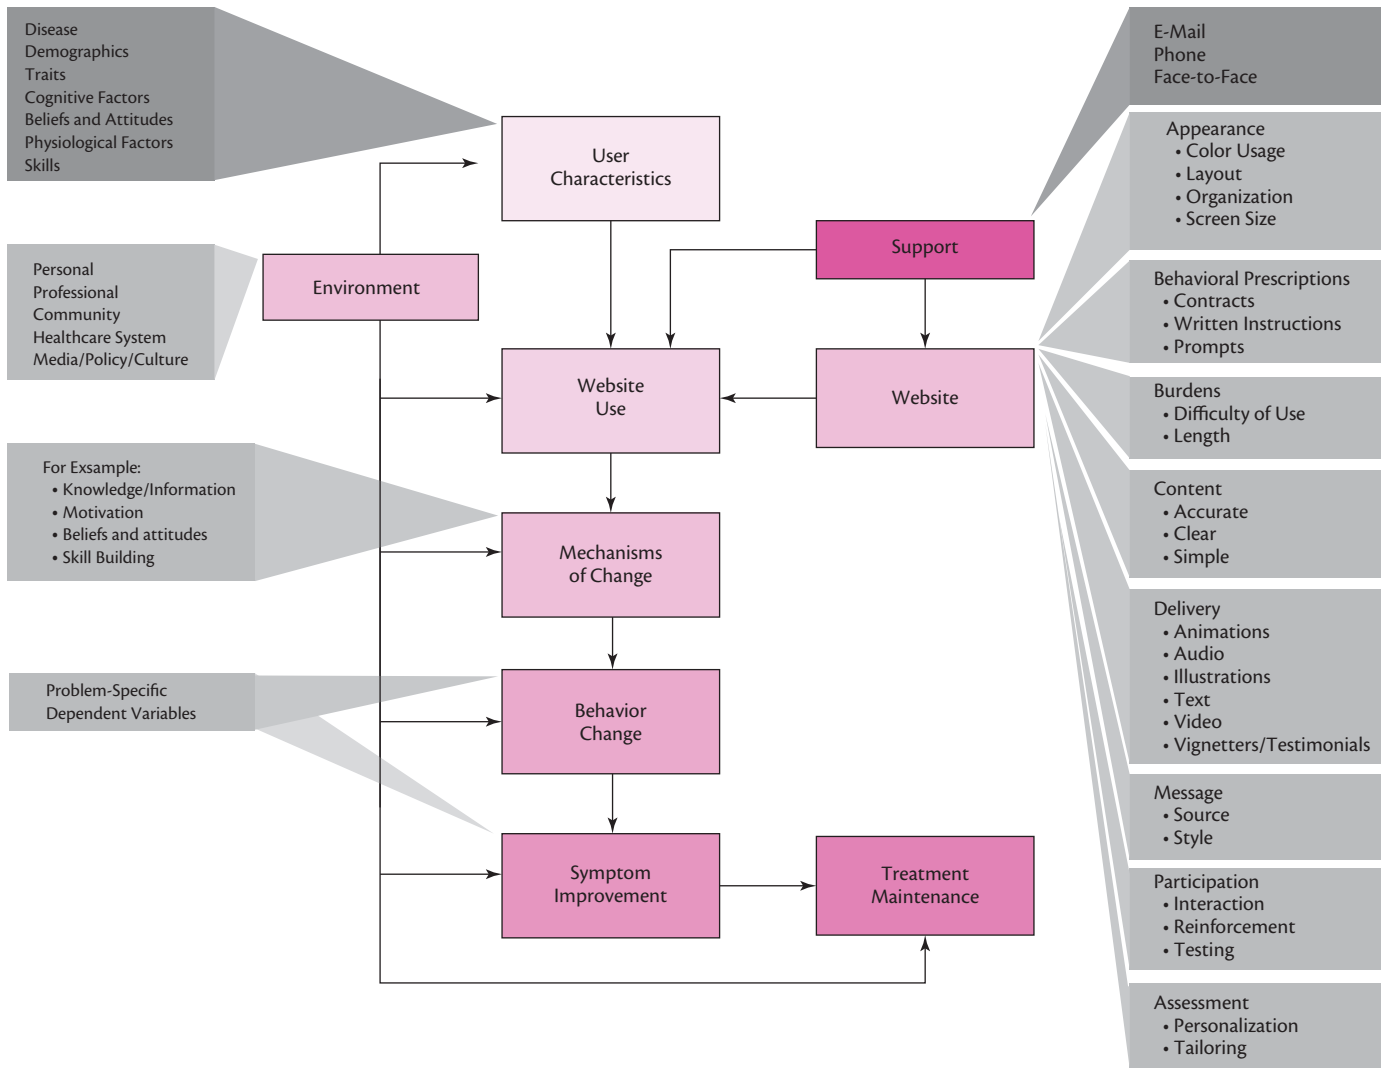

(Griffiths et al., 2006; Ritterband et al., 2003). Using ICT to deliver health interventions dramatically reduces geographic constraints, provides opportunities for access regardless of language spoken and travel constraints (financial or due to physical disability) and provides more immediate access to information that can help patients feel less isolated and more in control of managing their chronic condition (Griffiths et al., 2006; Nguyen et al., 2004).

Research into ICT-based psycho-educational and disease self-management interventions for adults has rapidly increased over the past decade, with results from systematic and meta-analytic reviews suggesting excellent efficacy for symptom reduction, knowledge attainment, and improved health behaviours across a wide range of chronic conditions including chronic pain (Cuijpers et al., 2008; Lorig et al., 2008; Murray et al., 2005; Nguyen et al., 2004; Palmqvist et al., 2007; Spek et al., 2007; Wantland et al., 2004). However, there is less empirical data on the availability and effectiveness of ICT-based psycho-educational and disease self-management interventions for children and adolescents with chronic health conditions (Cushing and Steele, 2010; Lelieveld et al., 2010; March et al., 2009; Palermo et al., 2010; Ritterband et al., 2003; Runge et al., 2006; Stinson et al., 2009). In the following sections, the evidence from treatment intervention trials and the advantages and disadvantages of telehealth, Internet-based programmes, and m-health (including smartphone apps) for management of chronic pain will be described.

## **Theoretical frameworks for ICT-based pain self-management programmes**

Murray and colleagues (2005) have developed a theoretical pathway to explain changes in health outcomes mediated by ICT (primarily Internet-based programmes). According to this pathway, ICT work by combining information with peer, decision-making, and behavioural change supports to allow internalization and interpretation of the information by the user. A combination of enhanced self-efficacy with motivation and knowledge, enables users to change their health behaviours leading to changes in clinical outcomes (Murray et al., 2005).

Ritterband and colleagues (2009) have built upon this postulated pathway of change by including characteristics of the end-users (i.e. demographic, disease, cognitive and physiological factors; personality traits; beliefs and attitudes; self-efficacy and skills), the environment, and the Web-based programme (see Figure 55.1) (Ritterband et al., 2009). While this model was based on Internet-based programmes, the key concepts are applicable to other ICTs as well. The model purports that programme users are influenced by environmental factors (i.e. family, friends, significant others, employers/school, health care system, community, and societal influences) which affect website use and adherence. Website use and adherence is also influenced by the type of support provided (e.g. email, phone, face-to-face) and characteristics of the website (e.g. appearance, behavioural prescriptions (e.g. contracts, prompts), content, burden (e.g. difficulty of use, length), delivery (e.g. animations, audio, illustrations, text, testimonials), message (e.g. source and style), participation (e.g. interaction, reinforcement, testing) and assessment (e.g. personalized or tailoring)). Finally, website use leads to changes in behaviour that results in symptom improvement through various mechanisms of change such as gaining knowledge, changing attitudes and beliefs, motivation, and skill building.

**Figure 55.1** Model of Internet interventions.

Ritterband et al., A behavior change model for internet interventions, *Annals of Behavioral Medicine*, Volume 38, No. 1, pp. 18–27, Copyright © The Society of Behavioural Medicine 2009, with kind permission from Springer Science and Business Media, <http://www.springer.com/medicine/journal/12160>.

## Internet-based chronic pain interventions

Improvements in Internet access and broadband speeds have led to an increase in Web-based treatments for chronic pain. Therapeutic Internet-based interventions are treatments based on effective face-to-face interventions (e.g. psycho-educational and CBT) that are transformed for delivery via the Internet with the goal of improved health outcomes (symptom reduction (pain and pain-related disability; decreased anxiety and depression) and improved health-related quality of life). Usually, Internet-based interventions are highly structured, self-guided or partly self-guided (i.e. minimal therapist support through regular brief telephone and/or email contact), tailored to the user's needs and interactive (Ritterband et al., 2003). While this is a burgeoning field, the Internet remains a relatively new medium for delivery of psychosocial health interventions. Formal evaluations of the impact of Internet health interventions on health outcomes, level of resource utilization and user satisfaction have lagged far behind intervention development (Danaher and Seeley, 2009; Nguyen et al., 2004).

The literature on Internet-based chronic pain interventions is rapidly growing with studies on feasibility and utility, as well as evidence of efficacy in improving clinical health outcomes being conducted (Lorig et al., 2008; Macea et al., 2010). Macea and colleagues recently conducted a meta-analysis of the efficacy of Web-based self-guided cognitive-behavioural interventions (4–7 weeks in length) with minimal therapist involvement (emails and/or telephone contact) for chronic pain. The primary outcome in this analysis was pain intensity. Eleven RCTs, including 2953 participants (67.5% women with mean age 41.32 (range: 7–91) years), with ten different pain-related disorders (low back pain and arthritis typically) were included. The pooled effect size (standardized mean difference between intervention and wait-list control group means) from a random effects model was 0.28 (95% confidence interval: 0.14, 0.42). Internet-based interventions resulted in significant changes favouring the experimental group in variables including medication use, health care visits, return to work capacity and pain reduction. In summary, the authors showed small treatment effects

for improvement of pain, greater improvements in pain-related conditions such as work disability and that CBT interventions are effective. All studies in this review used wait-list controls instead of placebo control, thus placebo effects remain to be examined in future trials.

More recently, Bender and colleagues conducted a systematic review of 17 RCTs of Internet-based pain interventions; however, this review incorporated both acute and chronic pain conditions (Bender et al., 2011). The 17 studies included interventions providing either CBT ( $n = 11$ ), moderated peer support programmes ( $n = 3$ ), or clinical visit preparation/follow-up support ( $n = 3$ ) to 2503 individuals in pain. Most Internet-based CBT trials (72.2%) used wait-list control conditions and three used comparable Internet-based control conditions. Interventions consisted of structured, self-administered therapy programmes offered in weekly modules that ranged in length from 6 to 20 weeks. All interventions included support from a clinical or research staff person via telephone, email, asynchronous or synchronous message boards. Minimal support typically included providing feedback on weekly reports, reminders to complete programme activities and administrative or technical assistance. Seven of eleven studies evaluated outcomes in adults and four evaluated outcomes in children and adolescents. The majority of studies showed improvements in pain ( $n = 7$ ; 77.8%), activity limitation ( $n = 4$ ; 57.1%) and costs associated with treatment ( $n = 3$ ; 100%), whereas effects on depression ( $n = 2$ , 28.6%) and anxiety ( $n = 2$ , 50%) were less consistent.

In addition, a review and meta-analysis of computerized CBT programmes for pain, aimed specifically at children and adolescents was conducted by Velleman and colleagues (2010). Four studies met the inclusion criteria and all demonstrated 50% reduction in pain compared to control groups that was maintained out to 3 months. Meta-analysis results suggested a pooled medium effect size of  $-0.41$  for reduction of pain intensity post-treatment with mean odds ratio of 0.63 for achieving clinically significant reductions in pain. These three systematic reviews provide growing evidence that Internet-based interventions reduce pain and pain-related disability. However, evidence on other important outcomes such as emotional functioning and cost-effectiveness compared to traditional face-to-face therapies remains to be determined.

While there are many advantages of Internet-based pain therapies; the current evidence suggests several limitations as well. For instance, given the self-guided nature and relative anonymity of this medium high trial dropout rates compared to traditional face-to-face therapies have been observed (Bender et al., 2011). However, adding human support via brief telephone/email contact with a therapist, or lay peers, and/or including social networking opportunities for intervention participants has improved motivation and adherence to online health care services, thereby optimizing the achievement of desired outcomes (Nguyen et al., 2004; Palmqvist et al., 2007; Rosser et al., 2011; Spek et al., 2007; Stinson et al., 2009). It is important that future studies collect information on reasons for dropout to inform the development of strategies to improve the adherence and efficacy of these interventions. In addition, motivational interviewing regarding readiness to change pain behaviours represents another promising method to help reduce dropout rates (Duff and Latchford, 2010; Vong et al., 2011).

## Social support in the age of the Internet

Social support is a multidimensional concept, which describes the formal and informal relationships developed to provide for the needs of individuals. Social support has been identified as a key factor in aiding patients in managing painful conditions and coping with related diagnoses (Rodham et al., 2009). Social support may take the form of peer education and peer networks fostering identity, empathy, and empowerment (Polomano et al., 2007); making it an important factor in establishing effective self-management behaviours.

Several positive health outcomes from social support have been identified in people with chronic pain. For instance, von Weiss and colleagues (2002) found that in children with painful rheumatic diseases, high levels of social support predicted lower levels of depression regardless of the level of daily hassle perceived to be due to the disease. Supportive social networks may also result in facilitating self-management behaviours and smoother transitions from paediatric to adult health care for adolescents with chronic painful conditions (Stinson et al., 2008; van Staa et al., 2011). Engaging in supportive and understanding social networks also results in improvements in long-term functional disability and pain in adults with rheumatoid arthritis (Evers et al., 2003). In addition, in adults with chronic pain, supportive social interactions resulted in reductions in negative mood feelings and improved perceived abilities to cope with their diagnosis (Feldman et al., 1999).

## Modern social networking

In recent years, the advent of the Internet and associated technologies has resulted in new means by which people may engage in socially supportive networks. Technology-based social networks have been used to connect people with members of existing communities, to build new communities and as modalities to disseminate and transfer knowledge (Henderson et al., 2012; Polomano et al., 2007; Scandfeld et al., 2010; Subrahmanyam et al., 2008). At present, social networking is amongst the most common reasons people access the Internet (Henderson et al., 2012). Technology-based social networking may take the form of electronic peer feedback generated from thoughts and experiences published on personal blogs and short Twitter messages or through more interactive discussion forums, online support groups and listservs (Barak et al., 2009).

The advantages of technology-based social networking opportunities for individuals with pain are many. Participating in blogging is postulated to act as an adjunct to other psychological and behavioural therapies by enabling self-reflection, debate and knowledge-exchange (Barak et al., 2009; Tan, 2008). Furthermore, the skills required to engage in online networking are relatively easy to learn and, in the case of children and young adults who have lived their entire lives in the age of the Internet (Henderson et al., 2012), are typically already possessed. Networks established via ICT have the added advantage of increasing accessibility to social support for people with pain. Online communication may act as a means to create social support networks, which would otherwise be difficult to build for persons with stigmatizing health conditions (Bargh et al., 2002; Henderson et al., 2012). Virtual communities can also facilitate interactions between people with chronic pain conditions. Peer-peer interactions may be problematic for those with rare medical presentations or those living in more remote communities. Research suggests that people with chronic and life-limiting health

conditions desire the ability to make social connections and seek social support from their peers with the same condition (Bender et al., 2011; Kearney et al., 2009; Stinson et al., 2008). ICT may circumvent this issue and increase accessibility to social support networks for all people with painful health conditions.

### Online social networking for people with pain

The limited number of studies ( $n = 2$ ) examining peer social support in adults with chronic pain show preliminary but positive effects on pain outcomes. These studies include a 2002 investigation by Lorig and colleagues into the use of an email-based listserv to connect people with pain. Peer support was provided in a second study through the use of an Internet-based asynchronous discussion forum (Lorig et al., 2008). Chronic pain conditions in these studies were recurrent lower back pain (Lorig et al., 2002) and arthritis (Lorig et al., 2008). Both of the interventions included group moderation by either peers or health care providers and in both cases, study sample sizes were large (range: 580–855). Peer support provided by the e-mail based listserv resulted in significant reductions in pain intensity, disability, and distress in the intervention group (Lorig et al., 2002). Use of the peer moderated discussion forum by people with arthritis resulted in significant reductions in pain intensity, distress, activity limitation, and improvements in health status (Lorig et al., 2008). However, neither study was able to show a reduction in health care utilization. In addition, clinically significant changes in health outcomes were not described in either study. A third study examined the effectiveness of using email-based peer support by adults with chronic low back pain to enhance the use of complementary and alternative medicine (CAM) modalities (Bruce et al., 2005). This study showed that participants in the intervention group did not differ from those in the control group, suggesting that peer support may be ineffective in enhancing the use of CAM therapies for pain.

Despite increasing interest in the prevalence and effectiveness of social support networking by people with pain, very little is known about how this group uses the most common social networking sites (although pain-related Facebook groups and Twitter handles do exist at present). Facebook, Twitter, and MySpace are some of the most widely accessed websites in use today. Facebook alone reports over 800 million members, with 400 million logging on to the site daily (Facebook, 2012). Social support networks for people with health issues have been established on these widely-used communication platforms often by patients or their family and friends (as opposed to health care providers; Bender et al., 2011). Created groups are typically informally moderated by more active group members and lack formal hierarchical organization.

In its early stages, Internet-based social networking appears to be a promising avenue to elicit accessible social support for people with pain; it is, however, not without inherent limitations. For instance, the majority of current social support networks are unmoderated and operate with little or no input from clinical or research experts. Given the sensitive nature of the information, opinions, and beliefs being expressed through these networks, monitoring by health care professionals or disease-specific organisations is warranted. In addition, support group websites should clearly present authorship details and disclaimers related to use. Health care professionals must also engage in conversations with patients about the benefits and drawbacks of participating Internet-based social support groups.

## m-Health technologies and pain

Mobile devices such as cellular phones and personal digital assistants (PDAs) represent another novel pain modality for monitoring and managing pain. In addition, the widespread use of mobile devices (85% of surveyed Americans) with increasing technical capabilities (Raine, 2010) increases the number of people electronic health interventions can reach. At present, several different mobile technology applications are being developed and tested for use in health care (Klasnja and Pratt, 2012).

The most basic of the mobile technology interventions is text messaging (short messaging service or SMS), a service allowing messages of 160 characters to be sent between mobile phones. Because the vast majority of mobile phones are capable of sending and receiving SMS, this service does not suffer from the potential drawbacks of more expensive devices (e.g. iPhones, BlackBerrys, devices with Android-based operating systems) and is commonly used in the developing world (Klasnja and Pratt, 2012). Potential health intervention uses of SMS technology include: (1) the logging of symptom data, (2) communication with health care providers and (3) the ability for patients to receive remote reminders to engage in health behaviours (Klasnja and Pratt, 2012).

A more complex use of mobile technologies for health condition management comes in the form of automated clinical decision support systems (CDSSs). The number of CDSS has increased greatly in the last two decades and CDSSs currently under development vary in their purpose and their intended user-groups (Moxey et al., 2010). Some are intended to provide health care professionals with evidence-based advice on how to proceed with patient care (Garg et al., 2005; Trafton et al., 2010). Others are designed in a 'shared-care' tradition and are intended to inform management strategies through direct use by patients (Gibson et al., 2010; Kearney et al., 2009). Because of the technical programming intricacies of these systems, they are typically available only on mobile devices that support more complex platforms, such as the iPhone or Android-operating system phones. At this time however, only a few evidence-based mobile technology-based interventions for pain management exist.

Recently, a review of 111 smartphone apps for the management of pain due to a wide variety of conditions was conducted (Rosser and Eccleston, 2011). Apps were targeted at a range of health conditions known to cause pain with the most common conditions targeted being headache or migraine (39%), followed by back pain (16%). The content of apps available at the time of review varied with 54% including education related to pain and its management, 24% including pain diary capabilities, and 17% including relaxation or meditation leading capabilities. Importantly, 86% of the apps did not report the involvement of health care professionals in content development and none have undergone rigorous evaluation using RCTs.

## m-Health technologies under development

### A mobile phone-delivered, and Web-based chronic pain intervention

A mobile phone-based intervention for people with chronic widespread pain has recently been developed and is in the pre-trial stages of effectiveness testing (Kristjansdottir et al., 2011). This intervention involves the remote delivery of CBT using SMS. The

study involved six participants (23–48 years) with chronic widespread pain who completed multidimensional pain diary entries for 4 weeks on phones. A therapist then remotely logged on to a secure website, viewed the diary entries, and provided individualized feedback aimed at stimulating patient self-management of the current pain situation. This intervention received high participant acceptability and usability ratings. In addition, compliance with diary entries was high (78–94% of entries completed) and technical problems with the intervention were infrequent and minor.

In developing mobile phone-based pain management interventions, researchers and developers should seek the expertise of health care professionals in the design and implementation of mobile pain management programmes to help ensure usefulness and safety. Rigorous testing of these interventions (i.e. via randomised controlled trials or RCTs) is also needed to determine their effectiveness. Successful evidence-based development of m-health interventions for people with pain may result in accessible care and improved outcomes, making research exploration in this area important.

## Telemedicine/telehealth

Telemedicine or telehealth refers to telecommunication systems in the broadest sense and includes the use of technology to help deliver and support health services (e.g. call centres, cell phones, video-conferencing, and web-based platforms). Telemedicine methods have been proposed as a means to improve access to pain management programming provided that appropriate therapists and remuneration policies are in place (MacDonald et al., 2011). A recent systematic review of telehealth for pain management found that only a limited number of RCT examinations of telemedicine versus traditional therapies exist (McGeary et al., 2012). However, based on currently available literature, there is good preliminary evidence to believe that telemedicine is an effective and viable means of managing pain (McGeary et al., 2012). The costing of telemedicine methods for pain management in adults with chronic pain has also been compared to traditional face-to-face therapies in a RCT (Pronovost et al., 2009). Results showed that direct patient costs were significantly lower in the telemedicine group than the face-to-face group and that more participants in the telemedicine group were satisfied with their consultation.

## Future directions for theory, research, and clinical practice

There is great excitement and opportunity associated with new ICT for the management of long-term health conditions such as chronic pain. While there is enthusiasm, there are a number of theoretical, research and clinical issues that need further consideration. First, consensus and standards on methods of development and metrics for evaluation of ICT-based health care treatments need to be developed. There is currently little guidance on how to develop or translate therapy from traditional human face-to-face to ICT-based delivery system. To this end, user-centred designs must be the starting point. The needs and perspectives of people in pain regarding ICT-based therapies (i.e. when and under what conditions ICT therapy is preferred to face-to-face) needs to be the first step guiding development of these interventions.

Despite the rapid adoption of these therapies, a technological divide does still exist in terms of age-related differences in technology confidence, skill, and use and the unequal provision of costly infrastructure (broadband computing) in different communities. The extent to which these interventions can be independent of any human support (lay person, trained non-health care professionals, health care professionals) is not known. There is evidence that self-guided or minimal human involvement is associated with greater patient dropout compared to face-to-face therapy. Determination of the minimum amount of support required to improve outcomes and the most appropriate person to provide that support is needed.

The essential ingredients that are needed in ICT-based programmes are also largely unknown and should be determined by conducting dismantling studies. We need to determine what types of patients are best served by these programmes and when in the pain trajectory, programmes are the most effective. In addition, the cost effectiveness of these programmes compared to traditional approaches needs to be determined. The cost of the development of these programmes can be reduced by developing a core set of pain coping skills that can be used across all types of chronic pain conditions. Clinicians and policy makers will need to rethink health care processes around chronic pain management to ensure funding to support the sustainability of these ICT-based therapies. Finally, we need to ensure data security, privacy, and confidentiality of personal health information.

In terms of research, standards on the reporting and evaluation of ICT have been recently established and will provide important guidance for future studies (Eysenbach and CONSORT-EHEALTH Group, 2011). Multicentred RCTs of high quality are needed to compare ICT-based treatments with active placebos as well as face-to-face CBT. Conducted trials should include the measurement of broader biopsychosocial outcomes and move beyond simple pain intensity examinations. Dismantling studies can help determine the optimal length of interventions, specific treatment components which are effective, and whether social support or therapist involvement would improve outcomes. Finally, strategies to reduce dropout rates (e.g. motivational interviewing and minimal online support) need to be evaluated.

## Conclusion

ICT-based pain treatments are an innovative way to improve the access and availability of psycho-educational pain therapies for individuals with chronic pain. There is growing evidence that ICT treatments not only reduce pain but also pain-related disability in various types of chronic pain conditions and in both paediatric and adult populations. We can continue to harness the potential of these mediums by ensuring that we explore the needs and perceptions of people in pain regarding ICT-based pain treatments—including when and under what circumstances the Internet is preferred to face-to-face therapies. This will help to tailor pain management efforts to individual preferences and enhance compliance and acceptability of these programmes. Moreover, well-designed studies with placebo control groups that include diverse patient groups are needed to strengthen the growing evidence base concerning ICT-based interventions for people with pain. Finally, we need to ensure that these programmes are publically available and that when they offer therapist involvement that this is remunerated by our health care system.

# Physical therapy interventions for pain in childhood and adolescence

Susan M. Tupper, Mary S. Swiggum, Deborah O'Rourke, and Michael L. Sangster

### Introduction: physical therapist perspectives on pain

Physical therapists (PTs) consider pain in young patients from three perspectives. First, pain is recognized as a symptom of an injury or disease, or the primary manifestation of the disease itself. From this perspective, pain is monitored over the treatment course and treatment effectiveness may be examined by the overall reduction in pain. Second, pain may be provoked during physical assessment. From this perspective, pain is a dichotomous event which is either elicited with a provocation test, or not elicited. Pain from this perspective is useful to support diagnosis and identify tissue structures that may be contributing to the symptoms, or to identify hypersensitivity or allodynia resulting from peripheral or central nervous system sensitization. Finally, pain may be an unpleasant consequence of treatment procedures. Discomfort that arises from the manual therapy, modalities, or prescribed therapeutic exercises (procedural pain) may be considered an adverse event (Chorney et al., 2010). From this perspective, PTs must be equipped to monitor for this reaction, and minimize or eliminate pain from treatment. This chapter will focus on interventions which are aimed at minimizing or eliminating pain from two of these perspectives: pain as a component of injury or disease and procedural pain.

The chapter is divided into four sections. The first section will provide an overview of the theoretical foundations that can be used as a framework for possible mechanisms of effect for physical therapy (PT) interventions and identification of PT interventions oriented towards maximizing participation of children with pain in valued roles and life activities. The second will review the literature on active therapies as interventions for children with pain. The third section will review the literature on passive therapies and safety and efficacy for manual therapy or therapeutic modalities for pain. The importance of the therapeutic relationship and pain education will also be discussed. The final section will review the

literature on procedural pain from a PT perspective and provide recommendations on procedural pain management. Although PT practice settings and the treatment needs of infants, children and adolescents with pain vary widely, this chapter will provide a structure for development of a theoretical and evidence-based physical therapeutic approach for all children with pain.

### Theoretical foundations in treatment planning

Knowledge of pain mechanisms has evolved from the notion of pain as a uni-directional consequence of peripheral nociception, to that of a complex physical and emotional experience with biological, psychological, social, environmental and behavioural influences. Similarly, PT treatment of pain is evolving from a tissue-oriented, bio-medical approach to both active and passive therapies with potential to modify nociception and pain through peripheral and central nervous systems (Flor and Diers, 2009).

Theoretical models of pain and function enable the therapist to conceptualize causal mechanisms of effect and to consider a comprehensive approach to management of pain. It is particularly important that PTs use a theoretical framework for selecting treatments in the absence of high-quality evidence to guide the treatment approach. Although evidence-based practice should be the paradigm for PTs, in many cases because of lack of research, treatments do not have strong evidence for effectiveness. Although future research may lead to more effective PT treatments and the development of treatment guidelines, a theory-based approach guided by regular evaluation of outcomes will serve in design and delivery of appropriate care. However, a treatment approach based only on theory does not necessarily ensure that the treatments provided are effective. Clinicians need the knowledge of the latest research, combined with frequent evaluation of the effectiveness of their treatments with each patient (Jewell 2011).

## Conceptual framework for pain

The neuromatrix theory will be briefly reviewed and discussed in terms of how it applies to PT treatment planning. The neuromatrix theory (Melzack, 1999) is a conceptual model for the genesis of pain that builds on the gate control (GC) theory (Melzack and Wall, 1970). The GC theory was revolutionary because it presented physiological mechanisms for bi-directional influences on pain and began to explain how competing peripheral afferent input (i.e. mechanoreceptor activity) and descending efferent activity from the central nervous system (i.e. emotional states or cognitions) could influence pain perception (Melzack and Wall, 1970).

The neuromatrix theory further reconceptualized pain as an output, or a 'neurosignature' which is generated by a complex neural network, the 'neuromatrix', as a noxious motivator to stimulate voluntary and involuntary actions that return the body to a state of homeostasis (Melzack, 1999). Melzack hypothesized that a pain neurosignature may be produced in the absence of identifiable tissue damage or disease and that the threat value assigned to the sensory information through conscious and unconscious cognitive and emotional appraisal will influence the sensory, affective, and cognitive dimensions of the pain neurosignature produced (Melzack, 1999).

Using this model as a framework, PT interventions for children with pain have three possible effects: (1) modification of the sensory afferent information, (2) modification of the cognitive and emotional evaluation (threat value) of the sensory information and (3) modification of the threshold for generation of the pain neurosignature by providing treatments that return the body to a state of homeostasis or regulate the stress-response systems (Figure 56.1). Because of the lack of specific research, PTs treating paediatric patients rely on knowledge of general neurophysiology or extrapolations from adult research to explain treatment effects. Research with children is needed to identify

the mechanisms by which PT treatments have an impact on pain in young patients.

Based on what is known about the neurophysiology of nociception, it is hypothesized that sensory afferent information may be modified either by reducing activity in peripheral or central nociceptive pathways, increasing competing sensory information, such as mechanoreceptor input, or increasing central nervous system descending inhibition of pain (Woolf, 2011). The goals of treatment with therapeutic exercises, manual therapies, and modalities are to alter nociceptive afferent activity either directly (e.g. transcutaneous electrical nerve stimulation (TENS)) or indirectly by reducing inflammation (e.g. cryotherapy) or modifying structural impairments and the biomechanical stresses on tissues (e.g. mobilization of scar tissue).

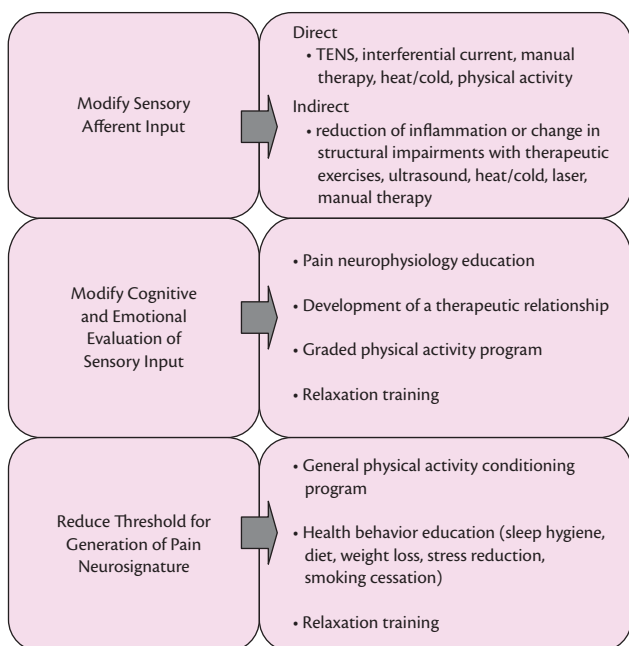

Education and change in knowledge and beliefs are hypothesized to modify cognitive and emotional evaluation of sensory input. Graded exposure to sensory stimuli that provoke fear or distress, in combination with development of coping skills may also alter the patient's evaluation of feared movements (Woods and Asmundson, 2008). For example, an adolescent with idiopathic persistent pain may avoid walking long distances with the misunderstanding that she is damaging tissues when she feels increased pain with activity. PT treatment for this patient may include education to address her beliefs and fear of pain with activity as well as a graded physical activity programme. Although the ultimate goal of the activity programme would be to increase muscle strength and cardiovascular conditioning, in the initial stages the exercises could be considered a form of systematic desensitization with gradual exposure to the movements or positions that she fears (Woods and Asmundson, 2008). These exposures, if paired with development of coping strategies to manage pain, may contribute to increased function and reduction of fear-avoidance behaviours.

PT treatments that aim to regulate the stress response would include general cardiovascular conditioning exercises, relaxation training, and education on sleep hygiene, diet, and healthy lifestyles. Management of acute or persistent pain must be conceptualized as one component of therapy oriented towards maximizing the child's participation in meaningful life roles and activities.

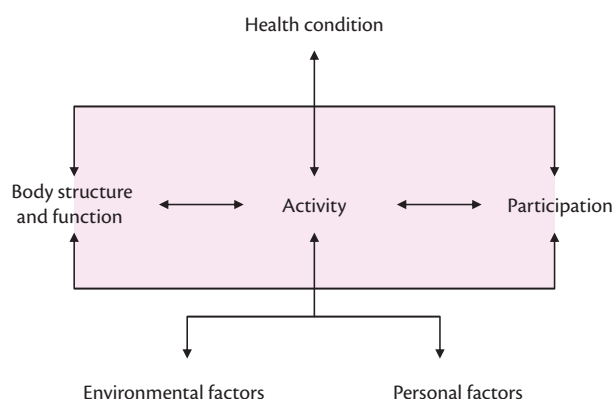

## International Classification of Functioning Disability and Health as a framework for treatment planning

PT treatment for the child with pain is typically one component of a broad interdisciplinary continuum of care. Use of a common classification framework for evaluation and treatment planning will facilitate communication between professions and ensure that evaluation, goal setting and interventions are comprehensive and oriented towards improving the child's participation in valued activities (Goldstein et al., 2004).

The World Health Organization's (2007) International Classification Framework for Children and Youth (ICF-CY) is a framework used to describe health as a state of maximum engagement in desired activities within a continuum of health states (Goldstein et al., 2004). The ICF-CY identifies two main categories for assessment: functioning and disability, and contextual factors. Functioning and disability are further subdivided into body functions and structures, activities, and participation (Figure 56.2). Contextual factors are an interrelated construct that can be subdivided into environmental or personal factors.

**Figure 56.1** Hypothesized mechanism of effect for pain relief from PT interventions.

**Figure 56.2** International classification of functioning disability and health model. Reproduced with permission from World Health Organization, ICF-CY: *International Classification of Functioning, Disability and Health Children and Youth Version*, Copyright © World Health Organization 2007.

Disability is an interaction between impairments in body structures and functions and environmental and social contextual factors experienced throughout life. For example, a school-aged child with juvenile idiopathic arthritis with impaired lower extremity function resulting from inflammation, pain, and loss of muscle strength at the knee may be limited in the ability to run or walk for long distances. This may restrict participation in after school activities such as a community basketball team.

The traditional approach to PT treatment focused on strengthening exercises and modalities to reduce pain and inflammation. A participation focused approach also includes an evaluation of the specific activities and may include evaluation within the specific environment where the child experiences the participation restrictions to determine if the environment or activities could be adapted to improve participation. Treatment planning would include traditional therapies to address the impairments in body functions and structures, but may consist of specific functional activities aimed towards improved participation and performance of the desired activities. For example, rather than providing a quadriceps strengthening exercise in isolation, the child may be provided with basketball drills that build quadriceps strength. This approach addresses the impairment in the context in which it is needed, and improves the child's motivation to participate in the intervention.

Treatment may also include modifications to the activities or environments in which they are performed, including prescription of adaptive equipment such as supportive braces as well as discussions with parents, teachers, and coaches to facilitate modifications that enable the child to fully and safely participate.

## Active therapies for pain in children

Across diverse health conditions, treatment adherence, health outcomes, and satisfaction with care are improved when children and adolescents are treated as partners and are actively engaged in making decisions about managing their health (Levetown, 2008). Active therapies include therapeutic exercises and general conditioning activities. Therapeutic exercises address specific impairments of body structures or functions such as limited range of motion of a joint or muscle, limited strength, impaired proprioception or balance or impaired cardiovascular conditioning. Therapeutic

exercises have been shown to be particularly beneficial for maintenance of functional outcomes and are recommended as part of a comprehensive treatment regimen for the management of patients with complex regional pain syndrome (CRPS; Bialocerowski and Daly, 2012).

Even in the absence of impairments, children are encouraged to be regularly physically active (Tremblay et al., 2011). General cardiovascular conditioning is important for short- and long-term health (Tremblay et al., 2011). International guidelines on physical activity for children (World Health Organization, 2012) recommend participation in 1 h or more of moderate (e.g. brisk walking) to vigorous (e.g. running) physical activity daily and aerobic activity should make up most of that hour. Children living with pain tend to be less physically active and have lower cardiovascular conditioning compared to their healthy peers (Maggio et al. 2010). Improvements in cardiovascular fitness will support the child's return to participation in activities of daily living and physical and social activities.

Many children living with persistent pain present with significant mobility limitations due, in part, to the belief that movement will cause further tissue damage. Fear-avoidance behaviours can affect all domains of the child's health and functioning and result in disability (McCarthy et al., 2003). It is essential to elicit parents' and children's beliefs about the causes of pain, factors they believe exacerbate and relieve the pain, and fears related to movement and physical activity and to address specific and erroneous pain beliefs with education and graded activity programmes (Ayling-Campos et al., 2011). Active PT interventions for children with persistent pain may require a significant change in movement-related behaviour. An assessment of the child's readiness to change and to participate in PT is important to include in the initial evaluation.

Motivational interviewing may be used to explore a youth's thoughts and feelings about the present functional abilities, discrepancies between the current state and wishes for the future, readiness to change, and confidence in the ability to make changes (Suarez and Mullins, 2008). Information gathered from the interview is used to design a PT programme that is individualized and tailored to the child's functional goals and reflects their interests and values (Ayling-Campos et al., 2011). By focusing on the child's goals, their motivation and self-efficacy is enhanced and their role as an active and capable partner in their health and functioning is acknowledged. Using the ICF-CY framework, this approach shifts the focus of therapy towards age appropriate activity and participation goals and away from the impairment of pain or other functional limitations.

Graded physical activity programmes are a primary component of PT interventions that are effective in reducing pain and improving physical functioning and participation (Woods and Asmundson, 2008). The following guideline has been used in prescribing graded exercise programmes for children with chronic pain. For each form of activity or exercise, the therapist determines the child's baseline, which represents 50% of that activity or exercise performed to tolerance (Eccleston and Eccleston, 2004). Tolerance can be determined either through the subjective history, or a physical performance test. For example, if a child's tolerance for walking is 10 min, their baseline for walking would be 5 min. Targets for increasing activity, both physical activity interventions and activities of daily living, should be negotiated between the therapist and the patient, and performance of activity each day should be based on these goals, not based on the pain experienced

(Eccleston and Eccleston, 2004). This 'pacing' approach provides a clear plan for progression with specific physical activity targets for each day. The probable mechanism of reduction of pain by activity pacing is through modification of the threshold for generation of pain neurosignatures by re-establishing homeostasis. However, it is also possible that graded activity reduces fear of movement through successful participation in gentle activities. As the child performs movements and activities without eliciting feared responses (e.g. flares of pain or incapacitation) the child may alter his or her cognitive evaluation of the sensory information from the movement or position as non-threatening.

Graded motor imagery (GMI) may be a helpful strategy to use early in the rehabilitation process for children who experience such severe pain that movement of the affected body part is not tolerable (see case example at the end of the chapter) (Moseley et al., 2012). GMI consists of three components that are introduced in a specific sequence: (1) laterality reconstruction where the child simply looks at pictures of hands or feet and identifies them as being left or right, (2) motor imagery training where the child is asked to imagine moving the painful limb and (3) mirror therapy which requires the child to place the painful limb inside a mirror box and watch the reflection of the unaffected limb as it appears to be the affected limb moving. Mirror therapy relies on a visual illusion to 'trick the brain' into assuming the painful limb is moving. GMI improved function and reduced pain in adults with chronic pain (Moseley et al., 2012).

## Passive therapies for pain in children

PTs are trained in the use of manual therapy and therapeutic modalities for treatment of pain and other functional and structural impairments in the body. There is currently limited evidence to support or refute the effectiveness or safety of these treatments for use with children. Passive therapies may have a place in the management of pain, particularly acute or procedural pain as they have the potential to modify sensory input and alter the production of a pain neurosignature; however, evidence is needed to support this hypothesis. In this section, the more commonly used passive therapies will be reviewed.

### Manual therapy

#### Mobilization and manipulation of the spine and extremities

The therapeutic effect of joint mobilization or manipulation for pain in adults has been reported in several randomized controlled trials (RCTs) and systematic reviews (Bronfort et al., 2010). Findings indicate generally favourable support for joint mobilizations or manipulation for acute or chronic non-specific low back pain without peripheral radiation, acute or chronic neck pain (when combined with exercise), migraine or cervicogenic headache, and several disease or injuries of the upper or lower extremities (Brantingham et al., 2009; Posadzki and Ernst, 2011). Studies on the effectiveness of joint manipulations or mobilizations in children have been primarily limited to non-pain conditions such as asthma (Bronfort et al., 2010). An RCT comparing spinal manipulations to sham manipulations in children with cervicogenic headache showed no difference between groups for days with headache, headache duration, school absence, analgesic consumption, or pain intensity (Borusiak et al., 2010).

Evidence to support the safety of PT manipulations and mobilizations of the spine and extremities for pain in children is lacking (Bronfort et al. 2010); therefore literature on the incidence of adverse events from osteopathic and chiropractic manipulations will be discussed. Serious adverse events such as permanent neurological impairments have been reported (Humphreys 2010). Retrospective file reviews reported incidence rates of adverse events with spinal manipulations in children ranging from 0.53% to 9% for minor adverse events such as temporary increase in signs or symptoms (Hayes and Bezilla, 2006; Miller and Benfield, 2008). No serious adverse events were reported in these three studies; however, retrospective chart reviews are prone to biases since there is not a rigorous standardized protocol or surveillance system, and results of these reports should be interpreted with these limitations in mind. Adverse events may be underreported by children, given that the incidence of adverse events reported in the adult literature is much higher, and underreporting of symptoms is typical of children (Morrow et al., 2012). The risk of serious adverse events in adults is estimated to be approximately 0.01% (Thiel et al., 2007). Skeletal immaturity at the growth plates results in a relative structural laxity and reduced resilience of the bone to withstand trauma in children (Scheuer and Black, 2004). The developing spine and soft-tissue structures should not be considered equivalent to adults for risk of adverse events.

### Massage

There is limited evidence to support the use of massage for the treatment of pain in children. Massage has shown moderate effectiveness for treatment of pain from burns (Parlak Gurol et al., 2010), headache (von Stulpnagel et al., 2009), juvenile idiopathic arthritis (Field et al., 1997), and in children attending an outpatient chronic pain clinic (Suresh et al., 2008). None of these studies were blinded and are therefore prone to biases. No studies were found that examined incidence of adverse events from massage therapy for the treatment of pain in children; however, based on the adult literature on adverse events, the rate is expected to be low (Ernst, 2003).

### Therapeutic modalities

Therapeutic modalities most commonly applied for pain relief include TENS, thermal agents (heat and cold), therapeutic ultrasound, and low-level laser.

#### Transcutaneous electrical nerve stimulation

TENS is an easy to use therapy that delivers an electrical current through a stimulation unit with electrodes attached to the skin. TENS is thought to decrease pain by delivering a competing sensation through stimulation of A-beta nerve fibres that reduce afferent nociceptive activity of A-delta and C nerve fibres if the stimulus is below pain threshold (conventional, or high-frequency TENS), or through stimulation of endogenous opiate production and descending endogenous neural pathways if the stimulus exceeds pain threshold (low-frequency, or motor-level TENS; Prentice, 2011). Settings for type of current, waveform shape, amplitude, duration, rate of rise and decay, and frequency can be modified to produce various physiological and therapeutic effects. Electrode size and placement can be altered to affect the depth and density of tissue stimulation.

TENS is effective in reducing acute and chronic nociceptive and neuropathic pain in adults (Nnoaham and Kumbang, 2008; Yameen

et al., 2011) and procedural pain in children (Lander and Fowler-Kerry, 1993). For pain relief, electrodes should be placed over or around the painful area or over the appropriate corresponding dermatome corresponding (Prentice, 2011). Alternatively, electrodes may be placed over muscle trigger points, acupuncture points, or superficial peripheral nerves. Since there is wide interindividual variability in response to TENS, several trials of electrode placement and nature of the current applied may be necessary to find the greatest pain relief for each client.

Many patients can be taught to apply this therapy with a pre-programmed light-weight, portable, battery operated unit at home. Pain relief with conventional TENS has a rapid onset (<1 h) for the majority of patients; however, pain levels typically return to pre-treatment levels within 1 h of discontinuation of the stimulation (Johnson et al., 1991).

### Thermal agents

PTs use heat and cold to reduce pain and inflammation through the use of warm or cold whirlpools, contrast baths, hot-packs (hydrocollator packs) or ice packs, ice massage, cryospray, warm paraffin baths, or fluidotherapy. Pain relief with the application of heat or cold is thought to occur through stimulation of the cutaneous nerve receptors and activation of A-beta nerve fibres with both heat and cold and reduction of rate of firing of nociceptive A-delta nerve fibres with tissue cooling (Prentice 2011). Physiological effects of increased superficial circulation with the application of heat, or decreased circulation with the application of cold can have indirect effects on pain through the reduction of muscle spasm or inflammation (Prentice 2011). Hot and cold packs, warm or cold baths and ice massage are inexpensive treatments that can be taught to patients for home use as a component of the PT regimen for management of pain.

### Therapeutic ultrasound

Therapeutic ultrasound delivers high-frequency sound waves (1–3 MHz) which produce thermal and non-thermal physiological effects with deeper tissue penetration than superficial thermal agents or electromagnetic radiation (Prentice, 2011). Ultrasound intensity, frequency, and pulse duration can be modified to alter the depth of penetration, and clinical effects. Ultrasound is thought to increase local blood circulation and tissue metabolism, thereby promoting soft-tissue healing, tissue remodelling, improved tissue mobility, and reduction of inflammation (Prentice, 2011). Pain relief is thought to occur through thermal effects.

Many studies reporting reduction of pain with ultrasound treatment have been criticized for methodological quality (Rutjes et al. 2010). However, there is evidence to support use of ultrasound for pain relief in adults with lower extremity osteoarthritis (Rutjes et al. 2010) and upper extremity musculoskeletal injuries (Green et al., 2003). No studies were found that examined ultrasound use for treatment of pain in children.

### Low-level laser

Low-level laser is a form of electromagnetic energy that produces little or no thermal energy with outputs of less than 1 milliwatt (Prentice 2011). Laser has been used for wound healing, reduction of oedema, scar tissue, and bone remodelling, and pain reduction with lateral epicondylitis, acute and chronic neck pain, osteoarthritis, and myofascial pain syndrome (Chung et al., 2012). Pain reduction is

thought to occur as a result of reduced nerve conduction velocities, anti-inflammatory or tissue healing effects (Prentice, 2011).

### Precautions and limitations of passive therapies

There are specific precautions and contraindications for the use of all thermal and electrophysical agents (Houghton et al., 2010). A qualified health professional such as a PT should be consulted for appropriate home use of modalities such as TENS. Therapeutic modalities may not be appropriate for children with vascular impairments, active infection, malignancy, recently radiated tissue, impaired sensation of the treatment area, and inability to communicate discomfort from the treatment (Houghton et al., 2010).

Therapists are urged to carefully weigh the benefits and limitations of passive therapies for children with persistent pain conditions. Given the limited empirical support and lack of evidence for safety for use with children and adolescents, passive therapies should only be used as part of a comprehensive, goal-oriented programme and not as a substitute for active therapies. Further research is needed to examine safety and effectiveness of these therapeutic approaches for pain in childhood. Although passive therapies may have a place in temporarily reducing symptoms, and may be particularly useful for treatment of acute or procedural pain, PTs are urged to use caution in the application of these therapies with children with persistent pain conditions. Injudicious use of passive therapies can provide false hope to patients for a 'cure' and foster dependence on passive therapies as a means of coping with pain.

### Therapeutic relationship and pain education

The relationship between the patient and the PT is integral to the therapeutic process and a predictor of outcome. PTs are uniquely positioned to develop a positive therapeutic relationship by virtue of the frequency and duration of interventions with children and their families. The provision of pain education through a family centred lens which is individualized to the patient is a vital component towards the development of a therapeutic relationship.

In a systematic review of 13 studies involving adults with several pathologies, the therapeutic alliance between patients and the PT was positively associated with improved treatment adherence, treatment satisfaction, physical function, and reduced pain (Hall et al. 2010). No studies were found that examined the impact of the therapeutic relationship between the PT and child with chronic pain on treatment outcomes during rehabilitation. However, children with chronic pain often report difficulties in encounters with health care providers such as a perceived lack of understanding of their pain experience, judgement, and disbelief. These unsuccessful healthcare interactions can lead children and their families to become disillusioned, develop a guarded approach and a tenuous relationship in dealing with healthcare professionals (Dell'Api et al., 2007).

Three main components of the therapeutic relationship have been identified patient and PT agreement on treatment goals, agreement on the intervention, and the affective bond between patient and PT (Daniels and Wearden, 2011). In a qualitative study involving 53 children ages 10 to 17 living with chronic pain, Meldrum et al. (2009) reported that solicitation of a pain narrative is an important part of the therapeutic process and that clinicians who were willing to listen to the child's story about his or her pain condition would be in a position to assist the child in making positive therapeutic changes.

This reinforces the importance of identifying patients’ functional, structural, and participation goals, and their expectations regarding the outcome of active and passive therapies. Agreement on the therapeutic goals and interventions can only be achieved with the provision of appropriate education about what are realistic expectations of therapy, and what actions on the part of the PT and patient are required in order to attain these goals.

Pain education should not be considered a one-way delivery of information from the therapist to the patient; rather, it is an opportunity to build the therapeutic relationship (Van Oosterwijck et al., 2011). PT specific pain education should address gaps between the child’s beliefs about the expected outcome of PT and the types of PT needed to achieve the child’s goals. It is essential to address misconceptions early in therapy and provide appropriate information to the child and his or her family on realistic outcomes from therapy regarding changes in pain, structural or functional impairments and return to participation in activities. It is also essential to address any misconceptions about the types of therapy that would be required to achieve the set goals. By providing information on pain neurophysiology and the expected outcomes from various therapies the PT can address these misconceptions and work with the child to develop a mutually agreeable plan for therapy.

Procedural pain management in children

Physical therapy procedures are increasingly being recognized as a source of pain for children receiving therapy services. Adults with cerebral palsy (CP) report that the pain related to PT interventions of stretching and bracing were the most salient negative memories of childhood (Kibele, 1989). The activity most frequently identified as painful by parents of children with CP was assisted stretching (Hadden and von Baeyer, 2002). Additional painful activities included independent standing, assisted walking, assisted sitting, and donning splints. Fifty-eight per cent of children with developmental disabilities reported pain during physical or occupational

therapy (McKearnan et al. 2004). Fifty-three per cent reported pain during a therapeutic home programme. Almost one-third of children with cystic fibrosis complain of pain during PT (Sermet-Gaudelus et al. 2009). The management of burn injuries is a source of pain and fear for children and their caregivers (Ratcliff et al. 2006). Clearly, there is evidence that the procedures commonly used by PTs to address impairments that accompany multiple childhood diagnoses are a source of stress and pain to the children and their caregivers.

Research is urgently needed to identify the prevalence and consequences of procedural pain from PT treatments, and pain-minimizing interventions that can be used during PT. This research is necessary to support the development of PT-specific guidelines towards eliminating unnecessary pain producing procedures and employment of prophylactic pain management techniques during procedures that are deemed necessary. As an example, this section will discuss pain management during stretching exercises with suggested strategies for reducing pain.

Pain management during stretching exercises

Stretching exercises are necessary for improvement of joint, muscle, and scar tissue range of motion for a variety of painful conditions such as CP, burns, muscular dystrophy, and juvenile idiopathic arthritis (Tecklin, 2008). Stretches may be performed independently (active), or with full (passive) or partial assistance (active-assisted) from a care-giver or health care provider such as a PT or PT aide. Interventions for pain management occur before, during and after the actual procedure. Table 56.1 provides an overview of examples at each stage.

Caregivers should be provided with information regarding the necessity and goals of the exercise, what will occur, and expectations of them during the stretches. Parents should be taught to avoid distress promoting behaviours, such as reassurance, apologies, or being overly empathic about the child’s pain (Chambers et al., 2002).

Table 56.1 Strategies for procedural pain management during stretching exercises

Timing	Strategy	Example
Before procedure	Prepare environment to facilitate relaxation	Private space for stretching in school to avoid unwanted peer attention
	Prepare child or caregiver for procedure with age appropriate language.	Sensory information: ‘Some people say this feels like a pinch, others say it feels like a pull. I want you to tell me what it feels like for you’
		Procedural information: ‘For this stretch you will reach up with both hands to touch that mark on the wall, like this (demonstrate). We’ll count backwards slowly from 20 and we’ll do that 3 times with a rest between each stretch’
During procedure	Pair non-pharmacological and pharmacological strategies	Time therapy with maximum pharmacological effectiveness or breakthrough medications
	Coping-promoting therapist behaviours	Prompt to use coping skill, non-procedural talk
	Cognitive-behavioural methods	Distraction (e.g. blowing bubbles, toys, storytelling, books, music, television, virtual reality), guided imagery, relaxation, breathing exercises, thought stopping
After procedure	Positions of comfort	Young child sitting in parent’s lap reading a book during manual therapy
	Reinforce use of coping strategies	Reinforcement: ‘You did great using your deep breathing during that stretch’
	Evaluate pain-relieving strategies	Was child able to tolerate procedure? Can procedure or coping strategies be modified to improve effectiveness or pain relief?

Source: data from von Baeyer, C.L. and Tupper, S.M, Procedural pain management for children receiving physiotherapy, *Physiotherapy Canada*, Volume 62, Number 4, pp.327–337, Copyright © 2010 University of Toronto Press.

Therapist behaviours also influence pain and distress responses during painful procedures. Miller et al. (2001) found that when PTs promoted use of coping strategies, there was reduced distress and increased coping in children with CP, whereas reassuring comments such as 'it's almost over' and criticism increased distress and reduced coping during rehabilitation.

Cognitive behavioural methods that may be appropriate to lessen pain experiences of children during PT procedures include distraction, guided imagery, relaxation, breathing exercises, and thought stopping (von Baeyer and Tupper, 2010). The PT or caregiver may reinforce the child's use of coping strategies by providing positive statements or tangible rewards, such as stickers, prizes, or praise.

The PT should reflect upon the procedure and evaluate the measures that were used to alleviate distress and pain responses. Questions to be considered include:

- ◆ Was the strategy appropriate for the child's developmental level?
- ◆ Are the parent and child satisfied with the strategy for prevention of pain?
- ◆ Was the strategy adequately effective in preventing or alleviating the child's pain?
- ◆ Was it paired with pharmaceutical interventions if appropriate (i.e. burn care or post-surgical rehabilitation)?
- ◆ If the procedure was experienced as painful despite appropriate measures, is there research to justify continuing with this procedure or can an alternative treatment be implemented?

## Recommendations

PTs are an integral component of multidisciplinary management of pain in children. However, in view of the paucity of evidence supporting the use of passive therapies for pain management in this population, therapists are encouraged to consider a comprehensive theory-based approach to treatment with an emphasis on active therapies. Treatment planning must be focused on returning children to patient or care-giver identified participation goals. Therapists are encouraged to provide opportunities early in the therapeutic process for the child to tell in their own words the story about their pain experience in order to identify treatment goals and establish a beneficial therapeutic alliance. Inactivity and fear of movement should be addressed through motivational interviewing, education, and graded activity programmes. Many PT procedures are painful for young patients, and therapists are recommended to consider applying a wide range of procedural pain management techniques to minimize or eliminate pain during therapy.

### Case example: mirror therapy for unilateral upper extremity pain

*Patient history:* Will, a 17-year-old male, was referred to PT by his palliative care physician, diagnosed with a nasopharyngeal rhabdomyosarcoma with an abdominal recurrence of metastatic disease. He received radical abdominal surgery including a nephrectomy, splenectomy, and distal pancreatectomy (see Box 56.1).

*Medications:* fentanyl and morphine as a part of abdominal surgery pain management. Gabapentin at 300 mg three times daily was added at the same time as the consult to PT.

*Physical therapy initial assessment:* On observation, Will displayed a left resting claw-hand deformity, wasting of the thenar eminence and first interosseous muscles, oedema, and significant colour changes (purple/blue skin colour over the dorsal and palmar surface of the left hand and all digits to the distal third of the forearm). Active and passive range of motion, resisted tests, and strength testing could not be performed due to intense pain. Sensory examination revealed left hand and forearm light touch allodynia with temporal summation, decreased sensation and increased pain in response to cold stimulus, and pin prick hyperalgesia. There was a positive modified upper limb neurodynamic test 1. Will's overall presentation was consistent with the Budapest clinical diagnostic criteria for CRPS probable type I (Harden et al., 2007).

*Physical therapy management:* PT management consisted of a 2-week trial of daily mirror therapy. CRPS is considered a central nervous system condition with changes to the primary motor and sensory maps that represent the painful body part (McCabe, 2011). Mirror visual feedback may correct sensory and motor remapping through short term cortical plasticity, thereby relieving pain. The mirror therapy approach involved Will placing his left hand behind a mirror which was situated in front of his chest in a sagittal plane. This positioning hid his affected hand from view, allowing him to view the reflection of his asymptomatic hand as if it were the affected side. Will performed a series of hand exercises with his right (asymptomatic) hand while observing this hand reflected in the mirror. Movement activities were structured according to difficulty and were tailored to simulate his treatment goals. Each session began with cardinal hand and wrist active range of motion followed by more complex functional tasks requiring more upper extremity dexterity. Mirror therapy was performed twice daily for 30 min each session.

*Outcomes:* Will reported immediate pain reduction following each mirror therapy session by 2 to 4 points on a 10-point scale which was maintained for an increased amount of time with each successive session. In addition, Will reported a significant decrease in the burning sensation and a 'more normal feeling' in his left hand following each session. After 2 weeks of daily mirror therapy, the distribution of his symptoms was reduced and Will reported his baseline pain at 5/10 which he now characterized as 'tingling' over the palmar aspect of the third digit. On physical re-assessment, Will displayed persistent wasting of the left thenar eminence and first interosseous, however the vasomotor and sudomotor changes observed on initial assessment were resolved. Full active range of motion of the hand, wrist, and forearm was observed. Sensory examination revealed the presence of residual pin prick hyperalgesia over the palmar aspect of the left third digit only. No allodynia and normal sensation to cold stimuli was noted. Despite persistent baseline pain at 5/10, Will was able to successfully return to playing video games after the 2-week PT mirror therapy.

## Acknowledgement

Susan Tupper is the Coordinator of Integrated Pain Strategy and Research for the Saskatoon Health Region, and Clinical Assistant Professor at the School of Physical Therapy, University of Saskatchewan.

**Box 56.1 Patient history for case example**

7-day history of acute left hand pain and decreased sensation following routine, uncomplicated arterial line insertion.

Initially located in thumb, spread to palmar aspect of his index and middle fingers within 24 h of onset, on removal of arterial line, pain spread through entire hand and was described as a 'glove' that extended to distal third of forearm.

9/10 (constant) on a 0 to 10 numeric rating scale, with 10 being maximum pain.

Burning, cutting, numbness, and tingling with spontaneous intolerable pain episodes characterized as 'lightning for no reason.'

Colour changes reported, unable to tolerate weight of bed sheet on hand due to intense pain.

Reported having no left hand function which limited ability to play video games; primary goal was to be able to return to playing video games.

## CHAPTER 57

# Occupational therapy

Liisa Holsti, Catherine L. Backman,  
and Joyce M. Engel

### Summary

Occupational therapists specialize in how pain impacts the development and maintenance of the occupations (self-care, productivity, leisure) of the daily lives of infants and youth in pain. Occupational therapists, working with families and other members of the health care team, use both generic and specific theoretical frameworks and models to guide clinical practice. These models ensure that a client-centred approach is used. In the everyday settings of the child, and using evidence-based practice, occupational therapists facilitate the treatment goals of children and families by integrating specific strategies, such as feeding, positioning, energy conservation, and adaptive equipment.

### Introduction

Infants born as early as 24 weeks of gestation respond peripherally, centrally, and cortically to nociceptive stimulation (Bartocci et al., 2006; Beggs and Fitzgerald, 2007; Fabrizi et al., 2011). Pain experienced early in life is associated with significant long-term consequences including functional alterations in pain processing, in stress-response systems, and in development (Grunau and Tu, 2007; Hohmeister et al., 2010). Not only is it unethical to let pain and suffering in infants and youths go untreated (Johnston, 2011), but failure to treat pain places this population at greater risk for negative health outcomes as they mature (Koupil, 2007; Sullivan et al., 2008).

As in adults, infants and youths can experience acute and chronic pain in a number of ways. Undergoing painful, medical diagnostic and therapeutic procedures may be necessary to sustain life for infants or those who are born critically ill, preterm, or who have an acute trauma requiring emergency care (Stevens et al., 2011). In addition, paediatric clients may experience pain associated with preventative health care (immunizations); with trauma, such as from burns or physical abuse; with disease processes (e.g. arthritis); or with physical disabilities (Engel and Kartin, 2004; Engel, 2011; Parkinson et al., 2010). Moreover, pain may be a primary reason for seeking health care services (e.g. over-use syndromes associated with computer use; Siu et al., 2009), or may occur as a result of rehabilitative procedures, such as stretching. Finally, pain may arise and continue without a readily identifiable cause, such as

with headaches. The most current reports estimate rates of pain in the general population of youths as high as 70% (Du et al., 2011), and self-reported pain in adolescents can be as high as 40% (Dunn et al., 2011) or higher (King et al., 2011). A more detailed review of the epidemiology of pain in children can be found in this volume in Chapter 2 by Stevens and Zempsky. Irrespective of the underlying cause, pain may limit an infant's, child's or youth's ability to perform everyday occupations necessary to maintain health and well-being.

### Background

The goals of occupational therapy for paediatric clients in pain are to develop, to maintain, and/or to restore their ability to participate in the occupations of their daily lives. Occupation has a broad meaning; it is everything people do to occupy themselves including activities related to self-care, to productivity, and to leisure (Townsend and Polatajko, 2007). For infants, the earliest occupations include changes in behavioural states and movements which indicate self-regulation and purposeful engagement with the environment (Holsti and Grunau, 2007a). For older infants and youths, self-care activities include engaging in their environment, feeding, sleeping, bathing, dressing, and mobility. Activities related to productivity are playing, participating in daycare and school, and in household, volunteer, or paid work. Leisure activities may also include play along with other tasks, such as social and recreational activities.

Early referral to occupational therapy services can prevent further disability and can provide critical support to family members. In order to understand more fully the unique contributions that occupational therapists make in restoring function and in mitigating pain in infants and youths, the purposes of this chapter are the following:

- (1) To describe occupational therapy theory and common practice frameworks.
- (2) To describe the impact/influence of pain on daily activities/occupational performance.
- (3) To describe the occupational therapy practice process for infants and youths with pain including assessment, goal-setting, intervention, monitoring and modifying treatment, and evaluation.

- (4) To describe occupational therapy intervention strategies used to treat pain in infants and youth.

## The occupational therapy perspective

### Occupational therapy theory

Theory is a tool for thinking about clinical practice. McColl and colleagues (2003) have classified occupational therapy theory, identifying generic and specific theories pertaining to everyday occupation, and a range of theories from ‘small t’ theory, such as theoretical ideas or propositions to ‘big T’ theory, encompassing more formal, well-articulated, and researched theoretical models (McColl et al., 2003). Occupational therapy professional organizations promote generic occupational therapy theoretical frameworks that identify occupational therapy’s domain of concern and foster communication and professional unity. For example, both the Canadian Association of Occupational Therapists (CAOT) and the American Occupational Therapy Association (AOTA) have published general theoretical references that form a basis for the education of occupational therapists and serve as national guidelines for practice. The Canadian Model of Occupational Performance and Engagement (CMOP-E; Polatajko et al., 2007) and the Occupational Therapy Practice Framework: Domain and Process (Framework-II; AOTA Commission on Practice, 2008) outline an occupation-based domain of concern. These models/frameworks provide the building blocks for thinking about the concepts that occupational therapists address in practice. They are generic models, applicable to any practice setting.

The CMOP-E, for example, explains three occupational performance areas—self-care, productivity, and leisure—as a way of classifying what people do in everyday life (Polatajko et al., 2007). Furthermore, the characteristics a person possesses are conceptualized as spiritual, affective, cognitive, and physical. Thus, this generic theoretical model guides an occupational therapist to consider assessing what is important to a child and what motivates that child to act (spirituality), their feelings and mood, (affective component), their capacity to learn and solve problems, (cognitive component), and their ability to move, (physical component), all in the context of their usual self-care, productive, and leisure occupations (bathing, dressing, eating; school or lessons; and play). Additionally, everyday occupations are performed in context—a social, cultural, institutional, and physical environment. Using CMOP-E, occupational therapy intervention can then focus on modifying the environment, the demands of the occupation, or the child’s skills in order to maintain or improve performance.

Similarly, the AOTA Framework-II describes how occupational therapy supports health and participation in life through occupational engagement. The concepts comprising occupational therapy’s domain of concern are client factors, performance skills and patterns, activity demands and areas of occupation, and context and environment (AOTA Commission on Education, 2008). These concepts provide a common language for thinking and learning about the way a child (or anyone) engages in the occupations they need and want to do throughout their lives, and the impact of individual and environmental conditions on that performance. In this framework, areas of occupation are defined as activities of daily living (ADLs, such as bathing and dressing), instrumental activities of daily living (IADLs, such as community mobility and safety), rest and sleep, education, work, play, leisure, and social

participation. Collectively, the conceptual framework guides the therapist to consider all areas of occupation as topics for assessment and intervention, together with the child’s performance skills and characteristics of the environment in which the child performs those occupations.

Both the CAOT and AOTA documents cited briefly offer generic models for thinking about practice with any client or client group. In contrast to generic occupational therapy theories, specific theories are those that explain particular concepts and the relationships among them that apply to a more targeted population, issue, or problem. Examples of these include sensory integration theories (e.g. Ayres, 1979), motor planning theories (e.g. Zwicker and Harris, 2009), neurodevelopmental theories (e.g. Wilson, 2005), and the gate control theory (Melzack and Wall, 1965) or the biopsychosocial model (Loeser and Fordyce, 1983). For neonates or infants, the synactive theory of development (Als, 1982) or the early life stress model (Loman and Gunnar, 2010) may also be used to inform assessment and treatment. Like other health professionals, occupational therapists often draw upon several theories simultaneously to inform thinking and action. In conjunction with process models, which provide a framework for action or problem-solving, generic and specific conceptual models guide professional reasoning.

The Occupational Performance Process Model (OPPM; Fearing and Clark, 2000) and Canadian Practice Process Framework (CPPF; Davis et al., 2007) are two process models that were designed to be compatible with the CMOP/CMOP-E and other conceptual theories. Both are step-by-step problem-solving processes to guide the identification of occupational performance issues or problems, the assessment or gathering of data about occupational performance areas, the child’s personal and environmental characteristics, the development of intervention plans, and the monitoring of the effect of interventions. The AOTA Framework-II illustrates how the concepts defining the domain of occupational therapy are inextricably linked to its problem-solving process, which centres on collaboration between the practitioner and the client/family (AOTA Commission on Education, 2008). This practice process has three defining operations: evaluation, intervention, and outcomes. Evaluation requires that the therapist identify the client’s occupational profile (what the child needs and wants to do) and an occupational analysis (the demands of the child’s occupations and the extent to which the child can engage in them). Intervention involves developing goals and plans, then implementing and monitoring the plan. The outcomes stage refers to selecting appropriate outcome measures and applying them to determine whether or not occupational therapy achieved the intended goals and contributed to the child’s health and participation in life (AOTA Commission on Education, 2008).

Importantly, occupational therapists working with children in pain are part of a team that includes other professionals, the infant or youth, and the family. Thus, other theories and process models may inform how the team works together to assess the situation and to develop an intervention plan. Occupational therapists may draw upon occupation-based theory to inform their specific contribution, as well as the team’s specific philosophy or interdisciplinary theoretical approach. For example, collaborative teams working with children and families in health, educational, or community settings may use biopsychosocial, developmental, social, and/or ecological theories of human development to ensure the needs of the child are met. Bronfenbrenner and Ceci (1994) introduced

a bio-ecological model of human development to explain environmental influences on the individual that crosses disciplinary boundaries. It has been tested, adapted, and applied to supporting children of all ages, and cited widely. Occupation-based theories are not only compatible with such approaches, but help to make the occupational therapist's role explicit to the team and to the family. Hickman and colleagues review empirical evidence on applying developmental and movement science theories to early intervention practices (Hickman et al., 2011). They indicate the importance of transdisciplinary approaches that support collaborative goal setting with the child and family as both a contributor to effective care and a challenge to maintain in complex care settings.

## How pain affects occupation

Children engage in a range of roles aligned with their developmental stage. For example, one of the roles of an infant is to engage in the environment purposefully to ensure its survival. Roles are supported by occupational engagement. Pain may prevent children from engaging in the occupations that contribute to, or are essential for, their life roles. One way to understand the potential impact of pain is to consider a basic occupational taxonomy (such as presented by Crepeau and Schell (2009) or Polatajko et al. (2004)) and how pain may interfere at any level of that hierarchy (see Figure 57.1).

Pain may inhibit an *action*: pinching a button; a *task*: buttoning a shirt; an *activity*: getting dressed; an *occupation*: completing morning self-care. As a result, pain at any level of occupational performance may limit the child's roles in life; in this example, the occupational therapist is concerned with supporting the child to develop independence in self care because it is a natural developmental milestone, and effective and appropriate dress contributes to participation in other roles, such as playing dress-up, being in uniform for a sporting team, or being dressed for school or church. Therefore, an occupational therapy assessment will identify which aspects of occupation are affected by pain; the strengths and resources the child has; and provide direction for selecting interventions that will overcome the effect of pain on the occupations the child needs and wants to do.

## Assessment

### Overall purpose and process

The purpose of the assessment is to establish a baseline that in turn informs goal setting and an intervention plan, and provides

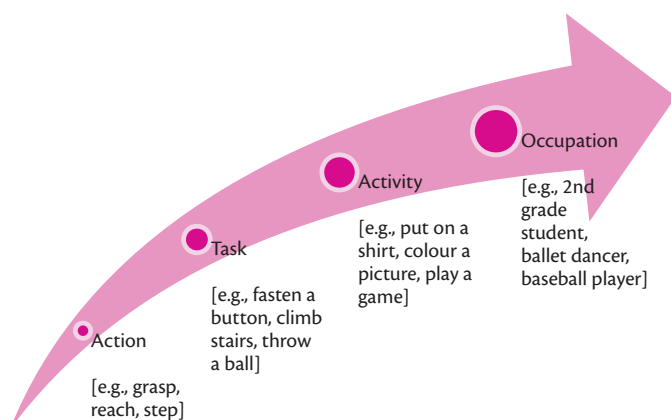

Figure 57.1 The influence of pain on childrens' occupational roles.

a comparator for later outcome evaluation to determine if goals were achieved. The process begins by screening for occupational performance issues—there is no need for more detailed assessment procedures unless the child's health status or symptoms, including pain, have an impact on or threaten occupational performance. An initial observation of an infant or an interview with the child and/or caregiver helps to identify specific problems and factors contributing to those problems, as well as resources to be considered in formulating an intervention plan. The assessment process may include observation, self-report, and performance-based tests in order to document baseline performance or identify individual strengths and limitations for choosing particular treatment modalities. In the presence of pain, it may not be appropriate or possible to conduct a complete evaluation in a single session or at all; priorities need to be established in light of the presenting circumstances. Although discussed as a discrete step, assessment is often ongoing and integrated into the intervention process.

## Infant assessment

Assessing pain in infants is complex for a number of reasons, the most obvious one being that infants are not able to self-report. Thus, occupational therapists must first assess the context in which pain may be present (e.g. as in postoperative pain or related to a disease process) and then rely upon a combination of behavioural and physiological indices shown to be the most reliable and valid measures of pain. For infants, these indices usually include specific, anatomically defined facial and body movements, changes in sleep/wake states, and changes in heart rate. Many of these indices have been included in a number of reliable and valid tools available for assessing acute pain in infants, such as the Behavioral Indicators of Infant Pain (BIIP; Holsti and Grunau, 2007b), the Premature Infant Pain Profile (PIPP; Stevens et al., 1996), the Neonatal Facial Coding System (NFCS; Grunau and Craig, 1987), the Comfort Scale (Ambuel et al., 1992) and the FLACC scale (face, legs, activity, cry consolability; Merkel et al., 1997). The psychometric properties of neonatal and infant pain tools have been reviewed extensively in this volume by Lee and Stevens (Chapter 35) and elsewhere (Stevens et al., 2007). Most recently, technologies, such as near infrared spectroscopy (NIRS) and electroencephalography (EEG) are providing researchers and clinicians with important complementary information regarding evaluating pain responses in infants at a cortical level (as reviewed by Holsti et al., 2011).

An important consideration for occupational therapists' assessment of pain is whether or not to use a tool that combines behavioural and physiological indices into a single score (a multidimensional approach) or to evaluate these categories of indicators separately (a unidimensional approach). This choice is important because in both infants and in children, dissociation between behavioural and physiological indicators is common (e.g. Morison et al., 2001). Including both behavioural and physiological indices is critical; however, if a multidimensional tool is used, and the effects of any applied treatments are not evaluated as to their effects on *both* the behavioural and physiological components, caregivers and researchers may miss important information as to the overall efficacy of the treatment. For example, sucrose is an oral solution given to infants to reduce acute procedural pain (Stevens et al., 2010). Although sucrose consistently reduces the behavioural component

of the pain response, its effects on physiological responses can be variable (Stevens et al., 2010). This type of 'split' response to a treatment raises the concern that failing to reduce the physiological response leaves infants vulnerable to the destabilizing physiological effects of pain.

To begin to address this issue, one study using NIRS examined the relationship between cortical pain responses and behavioural and physiological indices (Slater et al. 2008). High correlations were found between facial actions and cerebral blood flow; adding physiological indices did not improve the relationship. Although this research strategy shows promise for finding more accurate ways of assessing pain in infants, the fact that heart rate and oxygen saturation had only a modest relationship with cortical blood flow requires further exploration. Thus, more work is needed to determine which indices applied either in combination or individually will provide the most accurate reflection of pain processing in infants.

In addition to using standardized pain-related tools, occupational therapists can perform observational evaluations of the influence that pain may have on the infant's ability to engage in the environment, with their caregivers, during self-care activities and during play (Pierce et al., 2009). For example in a home setting, formal testing can be used to evaluate function and/or development, e.g. Peabody Developmental Motor Scales-2 (Folio and Fewell, 2000), The Test of Playfulness (Bundy et al., 2001), and combined with it, either through the use of a valid scale or by using parent report or informal observation, the contribution of pain-related behaviours as potential contributors to delayed or atypical development. Once the assessment is complete, goal setting with the caregivers can commence and treatment implemented.

## Infants and youth

One tool that assists more specifically with identifying occupational performance issues, goal-setting, and allows for both baseline measurement and subsequent outcome evaluation, is the Canadian Occupational Performance Measure (COPM; Law et al., 2005). The COPM is applicable to children of all ages; the parent or caregiver can be the informant for children not able to speak for themselves. It consists of a semistructured interview and rating scale. Up to five priority occupational performance issues are identified as intervention targets. After rating an issue's importance (on a 1 to 10 scale, 10 = extremely important), each one is rated in terms of the child's ability to perform it, and their current satisfaction with that level of performance, also on 1 to 10 scale (10 = able to do it very well; 10 = extremely satisfied). For example, Elly, age 6, chose jumping rope at recess, changing into a swimsuit independently for swimming lessons, and printing faster at school as important occupational performance issues. With some guidance from her mother and the occupational therapist to interpret the terms, Elly's baseline COPM ratings (see Table 57.1).

Subsequently, more detailed assessment techniques may be used to assess Elly's motor skills, the impact of pain on performance, and environmental conditions that might help or hinder performance. For other children, the issues and ratings may be from the parent's perspective (e.g. with an infant's parents, where the issues may be feeding, dressing, bathing, and playing with their child). Satisfactory psychometrical properties were reported in a clinical trial where the COPM was used with parents/caregivers of 42 children, ages 2 to 8, with cerebral palsy (Cusick et al., 2007), and in an interrater reliability study with the parents of 80 children, ages 1 to 7.5, with a range of disabilities (Verkerk et al., 2006). The latter study also found that the COPM identified individualized problems that were not captured by other standardized assessment tools (Verkerk et al., 2006). Using a tool like the COPM may facilitate assessment by identifying individual, functionally relevant goals to guide intervention and provide a concurrent outcome measure process. Skilfully conducted, the interview may also identify contributing factors to occupational performance problems that require additional assessment. It does not measure pain, but does provide a context for assessing the impact of pain.

A final example of an occupation-specific pain assessment tool is one which examines how pain interference impacts routine daily activities and participation. The Brief Pain Inventory Pain Interference (BPI) scale (Cleeland and Ryan, 1994) is a reliable and valid scale on which children or their caregivers rate on an ordinal scale of 0 (no interference) to 10 (complete interference) how much their pain has interfered with general activity, mood, walking ability, normal work, relations with other people, sleep, and enjoyment of life. Importantly, the BPI has been modified slightly for use with youths with physical disabilities (Tyler et al., 2002). The words 'walking ability' were changed to 'mobility (ability to get around)'. Persons who have mobility restrictions not related to pain (e.g. wheel chair users) can thereby rate the impact of pain on mobility. Self-care, recreational activities, and social activities items were added to be more inclusive of daily activities and participation that could be impacted by pain. 'Normal work' was changed to 'school or play'. The BPI can be helpful in determining baseline tolerance levels for specific occupations and participation as well as in evaluating outcomes before and after treatment (Tyler et al., 2002). In-depth discussion of behavioural pain assessment can be found in Section 5 of this volume (Chapters 35–41).

## Interventions

### Infants

Mitigating pain is vital to prevent the development of long-term changes in pain processing and in development associated with pain experienced in infancy. Pharmacological management, along with other forms of non-pharmacological management, is covered extensively in other chapters; thus the focus of this section will be

**Table 57.1** Elly's baseline COPM ratings

Occupational performance issue	Importance	Performance	Satisfaction with performance
Jump rope	9	4	2
Change into swimsuit	9	5	2
Print faster	8	5	5

to evaluate the efficacy of those treatments for which occupational therapists have specialized knowledge, including modifying the environment, positioning, feeding and play.

Occupational therapists have specific expertise in assessing the impact of the environment on everyday occupations (Polatajko et al., 2007). For infants undergoing procedural pain, occupational therapists can evaluate the infant's environment to ensure stimulation is modified to minimize pain. For example, evidence from two trials suggests that reducing environmental noise and lighting reduces both physiological and behavioural pain indices in preterm infants (Catelin et al., 2005; Sizun et al., 2002); however, the procedures evaluated in these studies were not skin-breaking, and environmental modifications were combined with other interventions. Thus, more research is needed to determine the relative contribution of environmental modification on pain in infants.

Occupational therapists can also use positioning strategies, including swaddling and facilitated tucking for pain reduction in infants. Swaddling is a strategy whereby an infant's arms and legs are tucked inside a blanket throughout the procedure. Alternatively, facilitated tucking is done by a caregiver who contains the infant's arms and legs with their own hands during the procedure (Figure 57.2).

In the most recent systematic review, sufficient evidence was found for both strategies for reducing pain indices in preterm infants ( $-0.75$ : 95% confidence interval  $-1.14$ ,  $-0.36$ ; Pillai Riddell et al., 2011). Nevertheless, many of the studies evaluating these treatments did not use blind evaluators nor did they account for order effects in those using a cross-over design; therefore, further research is needed to determine the benefits of these methods. Most recently, over five blood collections, facilitated tucking did not reduce pain indices (behavioural) as effectively as did sucrose, but did have an additive effect when used with sucrose; however, no differences in physiological indices were found (Cignacco et al., 2012). Currently, no evidence evaluating swaddling or facilitated tucking for older infants is available.

In addition to specializing in modifying the environment and using therapeutic positioning for managing pain, occupational therapists have specialized knowledge in the development of oral motor control and feeding. Indeed, feeding is considered a primary self-care related occupation of infants. For the purposes of

pain management, combining sucking and ingesting oral solutions, whether sweetened solutions or the more ecologically salient and potentially potent breast milk, may stimulate multiple pain relieving pathways (Holsti et al., 2011). Oral sweeteners have been used for mitigating pain in infants; however, more recent evidence suggests that they may be inducing mild sedation rather than providing analgesia (e.g. Slater et al., 2010). Some concerns have been noted regarding the methodology of this work (e.g. Stevens et al., 2011); therefore, these results require replication. In addition, sweeteners may have unintended negative effects on development when used in very immature infants over repeated events (Johnston et al., 2002; Holsti and Grunau, 2010). For a detailed review of the use of sweet solutions, readers are directed to Harrison et al. (Chapter 49, this volume). Further work is needed to understand the mechanisms of action of sweeteners and their effects long term.

Breastfeeding provides reduction of pain-related behaviours in infants born full term (Shah et al., 2009), for infants born preterm who have mature feeding skills (Holsti et al., 2011), and for infants up to 6 months of age (Dilli et al., 2009). A clear benefit to breastfeeding is that this treatment supports mother/infant interaction. Moreover, some have found breastfeeding to be more efficacious than sucrose (Codipietro et al., 2008) and than maternal holding (Leite et al., 2009), reducing both behavioural and physiological pain indices.

The timing of the treatment and the volume of breast milk/feeding ingested is important for maximizing its pain-mitigating effects (Holsti et al., 2011). For example, the infant must feed before, during and after the painful stimulus. If breast milk is given on its own, at least 5 ml of milk must be given in combination with sucking (Upadhyay et al., 2004). To date, no studies have compared full breastfeeding with the provision of breast milk on its own. Finally, feeding as a pain-relieving treatment should be used with caution because more study is needed to examine the use of this intervention over repeated painful events, particularly in infants born preterm, and to determine the effects of feeding on cortical pain processing to ensure this treatment is not acting merely as a sedative.

## Youth

For youth, occupational therapists can provide a variety of treatments aimed at mitigating or managing pain in a variety of settings, such as in hospital, in clinics, and of particular benefit is the application of treatment in the home. Indeed, home programmes are essential for transferring therapy skills from the clinic into the child's natural environments. Knowing the family's goals and activities are the first steps in determining realistic expectations for home programmes. Naturally occurring routines for teaching or reinforcing skills are sought as learning opportunities. After modelling individualized interventions, therapists should observe the family member's skill level in performing the therapeutic activity and provide guidance as needed. Written home instructions may increase the family's adherence with interventions. Therapists should strive for minimal disruption of daily routines within the child's environments. Family members' questions and concerns must be addressed. If the occupational therapist is treating an acute problem which may persist beyond a hospital stay, referrals to community resources may be needed to ensure that follow up care is maintained (Jaffe et al., 2010).

**Figure 57.2** Example of a parent providing facilitated tucking.

## Energy conservation

When assessment findings indicate that a child experiences increased pain with more intense or longer duration activities, or their participation in such activities is precluded by pain, then some collaborative problem-solving based on energy conservation, joint protection, and/or ergonomic principles may be helpful (Backman, 2011). A critical point is to help the child (and his/her supporters) to apply the principles to the specific activities and situations that are important to them with the aim of helping to balance activity and rest so that the child can participate as long as possible without pain and fatigue. Simply providing a list of principles and examples is generally insufficient—the child needs to be encouraged to figure out how to apply and modify the principles to situations in their own occupations. Although recommended for children (Kuchta and Davidson, 2008), evidence in support of joint protection (including splints) and energy conservation principles is largely limited to studies in adults (Hammond and Freeman, 2001; Steultjens et al., 2004).

Energy conservation principles include prioritizing, planning, positioning, and pacing. Pain saps energy reserves: one may need to set clear priorities in terms of choosing the activities in which to engage during a day, week, or other period of time. When children feel well, they will engage in play and other activities that interest them (Taylor and Erlandson, 2001). Once priorities are established, plans can be made for participating in the high priority activities, such as ways to get there, preparing or practicing ahead of time, obtaining appropriate equipment or assistive devices, if applicable. Positioning refers to awareness of body posture and positioning of the tools and equipment that support the activity or occupation. Placing frequently used items within pain-free/easy reach while working on school activities, games, or crafts is one example. Setting up a computer workstation to support a well-aligned posture is another. Lastly, pacing refers to 'listening' to how one's body responds to participation in the activity—what intensity or duration is tolerable or exacerbates pain—and adapting accordingly. Children will learn how to pace, how to adjust their involvement to accommodate their pain and their interest in performing an activity concurrently. When the activities are related to school, gym, or social groups, there may also be a need to teach teachers, coaches, and leaders about the intermittent nature of pain and pacing so that further pain and fatigue is prevented whenever possible.

Joint protection principles may help prevent or reduce pain for children who have either chronic joint conditions, such as juvenile arthritis, or an acute episode of pain from a musculoskeletal condition or injury. Joint protection principles include avoiding static postures and using the largest/strongest joints possible to minimize stress on smaller joints (Niedermann et al., 2011). Kuchta and Davidson (2008) offer numerous practical examples and handouts for children with rheumatic diseases, including strategies for managing pain (e.g. how to apply heat and cold) and modifying activities (e.g. choosing a backpack, planning car or plane travel, modifying gym class). These and other handouts can be printed from the publisher's web site (<<http://www.radcliffe-oxford.com/rheumaticdiseases/>>), and four have been included in this text as online supplementary materials. For example, carrying books in a messenger-style shoulder bag with the strap across the body protects the smaller joints of the hands and wrists compared to gripping a book bag or lunch bag. Using an appropriate sized backpack

is another alternative. In both cases, the weight carried needs to be matched to the child's size and strength. When it comes to textbooks, for those with pain, an even better alternative is to avoid carrying them back and forth to school by having a set at home and another set at school. The occupational therapist may be able to intervene with the school to justify the second set.

## Play/distraction

Play is also a primary occupation of infants and children (Bundy, 1992). With respect to the paediatric pain management literature, typically, distraction is the intervention studied, and the context is for managing acute pain. A number of different distraction strategies have been studied, such as showing an infant or child a novel toy or video, some being more effective than others. More specifically, whereas showing an infant a novel toy does not appear to modify behavioural pain responses in infants and young children (e.g. Cramer-Berness and Friedman, 2005), parents showing a video does appear to reduce immunization pain in this same age group (Cohen et al., 2006). These simple strategies require limited attention and visual engagement of the infant or child. A comprehensive review of distraction techniques by Cohen et al. can be found in Chapter 53 in this volume.

Alternatively or in addition, occupational therapists and other health care providers use therapeutic play for managing pain in a number of settings (Bandstra et al., 2008). Play is a complex activity requiring more interaction with the environment and incorporating more complex cognitive and sensory-motor processes than simple distraction. When more engagement is required by the child, that is, the child actually has contact with a toy and uses it or is immersed activity in a task, such as with virtual reality, pain is reduced (e.g. Law et al., 2011; Tanabe et al., 2002). For example, in a single-subject randomized design, Melcher-McKernan and colleagues (2000) found that in children with burn injuries, play activities were more effective in minimizing distress behaviours, maximizing activity and fun than were rote exercises. A more detailed discussion on the role of child life and recreational therapies by LeBlanc and Chambers can be found in Chapter 52 in this volume.

## Instruction in body mechanics

Back pain in youths is common (Kjaer et al., 2011). Instruction in and rehearsal of proper body mechanics and postures that will not increase the risk of low back injury are essential for clients experiencing both acute and chronic back pain. Practice in using the body safely and in maximizing performance during routine tasks in natural (i.e. homework, or leisure) environments is particularly important (Grangaard, 2011; Strong, 1996). The child should be taught to avoid tasks or positions that do not allow balanced posture.

## Adaptive equipment

To assist children maintain independence in routine daily activities, occupational therapists also can provide instruction for and provision of adaptive equipment (Howard, 2002). In particular, adaptive equipment is often needed for children with disabilities and to supplement therapy. Adaptive equipment includes such things as bathtub seats, high chairs, wheelchairs, car seats, and hydraulic lifts. The equipment is used to prevent abnormal movement patterns, muscle tone, positioning, and postures or support

more independent function. Adaptive equipment also prevents or facilitates correct positioning when the child is not being handled. Moreover, the equipment can be used to reinforce postures and movements introduced in treatment which can then be used in home programmes. Motor, sensory, perceptual, cognitive, and psychosocial development are also promoted with its use. Equipment should be restricted in its use as much as possible so as to allow the child's free exploration of the environment. Furthermore, any equipment should be monitored regularly to ensure the child's and family's needs and therapeutic goals are met (Aubert, 2008).

### Relaxation strategies

A variety of methods for inducing a relaxation response are available for managing pain. Progressive muscle relaxation (e.g. Barsky et al., 2010) or autogenic training (Payne, 2000), whereby clients are instructed in use of silently repeating seven standardized relaxation themes, are methods by which children can self-manage pain (for further details see Engel, 2011). These strategies should be integrated into the youth's daily routine, and the occupational therapist can help determine when the timing of these strategies might be most effective.

### Conclusion

Pain in infants and children interferes with their ability to engage in essential interactions with caregivers, with the acquisition of developmental milestones, and with participation in activities related to self-care, leisure, play, school, and work. Using occupation-based theoretical models, such as the CMOP-E and the Occupational Therapy Practice Framework: Domain and Process, provides a foundation for the provision of occupational therapy services to infants and youth. Through an iterative and continuous problem-solving process, occupational therapists provide standardized assessment of the infant's or youth's performance problems and along with the integration of the child's environmental context, develop and monitor the effects of interventions. Occupational therapists use specific treatment strategies such as feeding, positioning, splinting, and instructing in energy conservation and joint protection strategies, and the use of adaptive equipment. While some of the effects of these strategies have been evaluated rigorously in infants and children, as happens often in other areas of paediatric rehabilitation, some techniques have been applied based solely upon research conducted in adults. Thus, much more research is needed on assessing the benefits of occupational therapy interventions for mitigating both acute and chronic pain in children.

#### Case example

Patricia is the consulting occupational therapist for the local hospital neonatal intensive care unit (NICU) 2 days per week and for a community school 3 days per week. At the hospital, a new infant is admitted overnight who has a significant brain bleed and will require ongoing blood tests. The nurse asked that Patricia help teach the parents ways in which they can modify the infant's environment to support the infant's development and to help with pain management. Using the synactive theory of development (Als, 1982), Patricia describes how the environment in the NICU is developmentally unexpected and shows the parents how

to cover the isolette with a blanket to shade the infant's eyes. She explains how lowered lighting and noise can help stabilize the baby. She also describes how promoting flexed positioning will support the infant's motor development, and keep the baby calm. She shows them how they can work with their nurse to use facilitated tucking for providing treatment during blood tests. She begins educating the parents regarding infant behavioural cues which can be signs of stress and stability and how these signs are integrated into the unit standardized pain assessment scale so they can evaluate how well their facilitated tucking is working.

The following day at the school, Patricia receives a referral to see Ben, a 13-year-old student who has mild spastic hemiplegia cerebral palsy, but no cognitive impairment. Ben complains of daily, 30 to 90 min episodes of mild-to-moderate intensity leg pain exacerbated by prolonged ambulation, fatigue, and situational stress. The pain interferes mildly with mobility, stress management, and sleep as indicated by his importance ratings on the COPM of 8, 7, and 9 respectively. Ben rates his performance as 6 (mobility), 6 (stress management), and 4 (sleep), moderate satisfaction in these areas.

Ben received eight autogenic relaxation training sessions in his home for stress management and sleep difficulties. Importantly, this training does not require gross motor movement or muscle contractions, both problematic for Ben. Each 45 min weekly session consisted of information on stress and relaxation rehearsal. Ben was also given a relaxation tape to guide him through practice at home and school. Pain intensity (0 equals 'no pain'; 10 equals 'pain as bad as it could be') and tension levels (0 = 'completely relaxed'; 10 equals 'uptight/tense as you can be') were rated in a diary pre and post relaxation practice. Ben was weaned from relaxation tape use, and integration of relaxation and stress management strategies into daily routines emphasized. He was also instructed in strategies to promote restful sleep. Ben's family was instructed to encourage and praise his relaxation practice. Ben reported moderate improvement in reducing pain interference, especially with stress management and sleep.

Patricia's work in these two cases was guided by a practice process of assessment, intervention, and outcome evaluation; her clinical reasoning was informed by theory. By assessing the interaction between the infant's developmental stage and the NICU environment, with an occupation focus, Patricia's recommendations enable the parents to engage with their baby (parenting role, nurturing occupation). Drawing on a specific theory related to infant development, Patricia's intervention plan minimizes threats to the infant's future occupational performance.

Into Ben's routine at home and school, Patricia integrated specific pain-relieving modalities thus facilitating his occupational roles. An outcome measure at baseline allowed for later outcome evaluation, showing progress toward achieving Ben's goals.

## CHAPTER 58

# Mother care for procedural pain in infants

Celeste Johnston and Marsha Campbell-Yeo

### Summary

A major role of maternal care is to protect their infant from harm, including pain. The aim of this chapter is to review the evidence on the effectiveness of maternal strategies that are efficacious in managing procedural pain including breastfeeding, kangaroo mother care, and facsimiles of maternal presence such as voice recordings, odour, and other care providers. The mechanisms, as currently understood, underlying the efficacy of maternal care, will be presented. Finally, pragmatic issues, such as feasibility, will be discussed.

### Introduction

Mammalian mothers almost universally take care of their young. This includes providing nourishment and protection from harm. Protection from harm, in the event of tissue damage, encompasses providing comfort to assist the infant to return to a pre-injured state. In modern human history, particularly in developed countries, ill or very preterm infants are separated from their mothers, who then lose the nurturing and protective roles that are inherent in motherhood. Even well babies undergoing routine medical care are often separated from their mothers. Infants are often removed from their mother's arms and placed in a bassinet to undergo a painful procedure. This separation is executed in the belief that health care professionals can care for the infant without the mother, and, in fact, that the mother may interfere with their ability to give the most efficient care to the infant (Campbell-Yeo et al., 2008b). As paediatric hospitals and units move towards family centred care, this separation is being questioned (Franck et al., 2011). Recent reports from the literature can be used to support the inclusion of parents, especially mothers, in the care of hospitalized infants including the role of providing comfort during painful events.

### Background

#### Breast milk, breastfeeding

Breast milk and breastfeeding are often considered together for obvious reasons: you cannot have breastfeeding without breast milk or its precursor, colostrum. In full-term neonates, Gray and colleagues reported there was significant reduction in pain scores with breastfeeding compared to standard care (Gray et al., 2002). Other

studies, compared breastfeeding to sweet taste with mixed results. Bilgen found 25% sucrose more effective in decreasing heart rate change, crying, and recovery time (Bilgen et al., 2001). Carbajal et al. (2003) reported equivalent reduction in composite pain scores between breastfeeding and glucose plus pacifier. Codipietro et al. (2008) reported significant differences on pain scores favouring breastfeeding over sucrose. Finally, Gradin et al. (2004) reported that in combination, there were synergistic effects between 30% glucose plus breastfeeding. Results from a systematic meta-analysis of breastfeeding support its use as a comforting measure for procedural pain in full-term infants (Shah et al., 2007). Pain scores measured using the Premature Infant Pain Profile (PIPP; Stevens et al., 1996, 2010) composite pain measure were significantly different between the breastfeeding group and the placebo group (weighted mean difference: -6 (range -7 to -4)), but these scores were not different when compared with the glucose plus pacifier group (weighted mean difference: 1.30 (range: 0.05 to 2.56)) (Shah et al., 2007).

Breast milk delivered by syringe alone (i.e. without a pacifier or being held) is, in all but one study (Upadhyay et al., 2004), ineffective in reducing pain (Bilgen et al., 2001; Blass, 1997; Blass and Miller, 2001; Ors et al., 1999). This finding is hypothesized to be relative to the sweetness of sugars; where lactose in breast milk is much less sweet than sucrose (Joesten et al., 2007; McDaniel et al., 1989).

These results raise certain questions about why breastfeeding is effective, since breast milk administered alone is not. Sucking could be one component since sucking alone has been reported to have a pain reducing effect (Bo and Callaghan, 2000). Maternal closeness could be another factor. Holding by the mother was more effective in reducing crying than both holding and sucrose alone but facial actions of pain were decreased only by holding (Gormally et al., 2001). However, in another study, holding by mother was not as effective as glucose on pacifier or breastfeeding (Carbajal et al., 2003).

The evidence to support breastfeeding as a comfort measure is strong (Campbell-Yeo et al., 2011). At its weakest, breastfeeding is marginally less effective than sweet taste, but the results are mixed. The underlying mechanisms are likely synergistic since neither holding, breast milk alone, nor sucking alone can explain its effectiveness. For a more in-depth discussion on sucrose and sweet taste in relieving pain in infants, please see Harrison et al. (Chapter 49, this volume).

## Skin-to-skin contact, or kangaroo mother care

Skin-to-skin contact (SSC) between infant and mother is commonly referred to as kangaroo mother care (KMC), due to its similarity to marsupial maternal care. Among behavioural and physical interventions for procedural pain in the neonatal intensive care unit (NICU), SSC is of interest both because of its effectiveness, but also in its centrality to family centred care. Currently, the comforting role of mothers is lost in the typical NICU setting (Montirosso et al., 2012). Yet, pain their child experiences and the loss of that comforting parental role are among the highest sources of stress for mothers as well as fathers (Franck et al., 2005; Miles et al., 1989, 1993). By giving mothers an opportunity to take on the comforting role of parenthood, they feel they are effective and closer to their infant (Campbell-Yeo et al., 2008a).

KMC was implemented in the modern era as an alternative to the incubator to maintain preterm infants' body temperature and increase survival rate in South America where incubators were in short supply (Charpak et al., 1994). During this time, it was serendipitously noted that infants spent more time in quiet sleep state (Ludington-Hoe et al., 2006). More recently, analysis using electroencephalogram (EEG) sleep studies demonstrated that preterm infants exposed to KMC daily for 8 weeks had fewer rapid eye movements, more quiet sleep, and less spectral beta when compared to full-term infants, delivered at term or delivered preterm and corrected to term equivalent who did not receive KMC (Scher and Loparo, 2009). Since quiet state is associated with decreased pain response (Grunau and Craig, 1987; Stevens et al., 1996) the idea developed to use KMC for procedural pain management.

The first study examining the effect of KMC and pain response was conducted by Gray in 2000, in full-term neonates where decreased crying and a lower heart rate acceleration were observed (Gray et al., 2000). Three years later, Johnston, in the first study examining KMC with preterm neonates undergoing heel lance, reported a decrease in composite pain scores, as well as the individual components of decreased facial action, lower heart rate acceleration, and increased oxygen saturations for neonates receiving KMC compared to incubator care (Johnston et al., 2003). A 2-point reduction as measured using the PIPP (Stevens et al., 1996) was found at 30, 60, and 90 sec after heel lance (Johnston et al., 2003) and at 90 sec ( $p < 0.001$ ) in a similar study by Johnston examining the pain response of very preterm infants (Johnston et al., 2008). An even larger difference was found by Akcan et al. (2009) at 1, 2, and 3 min after heel lance or venepuncture (mean PIPP score of 7, 4, and 4 in the SSC group and 15,  $p < 0.001$ , 15.5,  $p = 0.001$  and 15,  $p = 0.047$  in the control group). In a Cochrane review on SSC for procedural pain in infants, 15 studies that meet the inclusion criteria all showed positive results (Johnston et al., 2010) when compared to usual care (see Table 58.1). Two studies (Chermont et al., 2009; Freire et al., 2008) showed that KMC/SSC was more efficacious than sweet taste.

## Auditory facsimiles of maternal presence

While infants are *in utero*, sensory learning is taking place, so that following birth, they have some knowledge of their mother's identification, notably auditory and olfactory (see later sections). During the third trimester ( $\geq 27$  weeks GA) fetuses are able to hear and respond behaviourally to sound and auditory stimuli (DeCasper and Fifer, 1980; Ockleford et al., 1988). DeCasper and Spence

(1986) studied pregnant women at 30 weeks of gestation who had recited a target story aloud to their fetuses twice daily until birth. At birth, the target story had greater reinforcing value (measured by sucking bursts) to the novel story and was independent of who recited the story. In another study, pregnant women at 33 weeks of gestation recited a target rhyme three times daily for a succession of 4 weeks which the fetuses differentially responded to with a brief decrease in fetal heart rate (DeCasper et al., 1994). DeCasper and Fifer (1980) examined full-term newborns within 3 days of life, and found that they preferred their mother's voice more than a female stranger's voice. In addition, the newborn, up to 8 months in age, can discriminate and show preference for their mother's voice compared to a female stranger's voice (Standley and Masen, 1990). Fifer et al. (1995) found that newborns suck a non-nutritive nipple significantly more often when syllables are paired with the maternal voice to syllables paired with another woman's voice or silence. When presented with a choice of hearing their own mother's voice in speech or a filtered version in such a way as to mimic womblike sounds, newborns suck more often to the signal predicting the '*in utero*' versions of their own mother's voice.

Based on these data of infant auditory memory of their mother's voice, as well as memory of maternal heartbeat, auditory recordings compared THE EFFECTS OF recordings of maternal sounds have been tested on pain response in infants. The first study with full-term neonates compared recordings of maternal heartbeat to Japanese drum (the study was conducted in Japan and the Japanese drum is soft and rhythmic) on salivary and serum cortisol response following heel stick (Kurihara et al., 1996). Maternal heartbeat was more effective in decreasing behavioural indicators of stress, measured using facial and vocal response during heel lance as well as cortisol levels measured 20 min post lance. More recently, maternal voice recordings of babytalk, nursery rhymes, or songs, played to preterm neonates during quiet time and then during a heel lance procedure was no more effective than usual care with no sound (Johnston et al., 2007). In this study, the decibel levels of the recordings were above the recommended levels, as was the ambient noise of the study NICU, which may have interfered with the infant's ability to process the actual sounds.

## Maternal olfactory effects on pain response

There is similar olfactory as well as auditory learning of mother *in utero*. When newborn infants, separated from their mothers, were exposed to amniotic fluid, their mothers' breast odour, or no odour, the ones who were exposed to amniotic fluid calmed more quickly and cried less (Varendi et al., 1998). Furthermore, in another study of infant preference measured through head turning towards odour, infants showed recognition of their own mother's amniotic fluid, versus amniotic fluid from other women (Schaal et al., 1998). Full-term infants also preferred the smell of human milk, not necessarily their own mother's milk, over formula milk (Marlier and Schaal, 2005). Thus, the potential use of the familiar maternal odour was tested as an intervention for procedural pain in newborns.

Goubet and colleagues conducted three studies on familiar odours versus non-familiar odours on pain response in full-term infants (Goubet et al., 2003, 2007; Rattaz et al., 2005). All studies demonstrated the effectiveness of a familiar smell, be it from mother or from conditioning the infant to the smell of vanillin. One study compared odours of mother's own milk, another woman's milk, formula milk, or no odour control on grimacing, crying,

**Table 58.1** Studies examining the effect of kangaroo care (KC) on pain response

Study	Sample N, GA	Design and intervention	Provider	Procedure	Outcome measures	Results in KMC
(Gray et al., 2000)	30, full term	RCT, 10–15 min, KC vs swaddled in cot	Mother	Heel lance	Duration of cry, grimacing, HR	Cry ↓ by 82%, grimacing ↓ by 65%, smaller ↑ in beats/minute during blood collection (8–10 vs 36–38)
(Johnston et al., 2003)	74, 32–36 weeks GA	RCT, crossover 30 min KC vs swaddled in incubator	Mother	Heel lance	PIPP: facial actions, heart rate, oxygen saturation, gestational age, behavioural state	PIPP scores significantly ↓ at 30 sec (MD, 1.5 points; $P = 0.04$ ), 60 sec (MD, 2.2 points; $P = 0.002$ ), and 90 sec (MD, 0.6 point; $P = 0.37$ ) after heel-lancing procedure. Heart rate and oxygen saturation similar in both conditions. Facial actions contributed significantly to total pain score ( $0.000 < P < 0.005$ ), with facial actions averaging 20% greater in control vs KC condition.
(Ludington-Hoe et al., 2005)	23, mean 31 weeks GA	RCT, crossover 3 h of KC vs incubator	Mother	Heel lance	HR, respiratory rate, oxygen saturation, ↓ crying, length of crying, behavioural state	Mean rise in heart rate ( $F(1,32) = 3.01$ , $P = 0.047$ ) from baseline to heel lance was less in the KC condition than in the warmer condition. Crying length during KC heel lance significantly less than during warmer heel lance ( $F(1,32) = 7.38$ , $P = 0.003$ ) and post-lance period ( $P = 0.02$ ).
(Kashaninia et al., 2008; Sajedi et al., 2007) <sup>a</sup>	100 full term	RCT, 10 min KC vs cot	Mother	IM injection	Duration of cry, NIPS score	Mean duration of crying post injection was longer, 24.61 in the control group vs 14.55 sec in the KC group $p = 0.001$ . NIPS scores significantly ↓ immediately following injection in KC, $p < 0.001$
(Castral et al., 2008)	59, 30–37 weeks GA	RCT, 15 min KMC vs swaddled in incubator	Mother	Heel lance	Facial action, NFCS score, behavioural state, duration of cry, HR	NFCS score significantly ↓ at heel lance ( $-1.140$ ; $p = 0.23$ ) and squeeze phase ( $-1.872$ ; $p < 0.001$ ). Cry ↓ by 37.4%. No difference in HR
(Freire et al., 2008)	95, 28–36 weeks GA	RCT. 15 min KC vs oral glucose vs prone position in incubator	Mother	Heel lance	Behavioural state, HR variation, Oxygen saturation, PIPP scores for facial actions	No difference in behavioural state, ↓ variation in ( $p < 0.0001$ ) and HR in oxygen saturation ( $p < 0.0012$ ), ↓ scores for facial actions ( $p < 0.0001$ )
(Johnston et al., 2008)	61 28–31 weeks GA	RCT cross-over 15 min KC versus swaddled in incubator	Mother	Heel lance	PIPP, time to recover (heart rate return to baseline), facial actions, HR, oxygen saturation	PIPP scores ↓ at 90 sec (8.871 versus 10.677; $p < 0.001$ ). Time to recover ↓ in KC (123 sec (95%CI 103–142)) vs 193 sec for incubator (95% CI 158–227) ( $F(61,1) = 13.6$ , $p < 0.000$ )
(Kostandy et al., 2008)	10 Preterm 30–32 weeks GA	RCT, crossover, 30 min KC vs nested in incubator	Mother	Heel lance	Audible and inaudible crying (Anderson Behavioural State Scoring system)	↓ combined crying time during heel stick (55 vs 96.2 sec; $p = 0.001$ ) and during recovery (5.8 vs 25.5 sec; $p < 0.01$ ). Inaudible cry was minimal in each phase, in both conditions 0–1.34 sec
(Akcan et al., 2009)	50, Preterm 26–36 weeks GA	RCT, 45 min KC × 5 days-procedure on 5th day.	Mother	Heel stick/venepuncture	PIPP score at 60, 90, 120 seconds following procedure	PIPP scores were ↓ in the KC group, at the 1st, 2nd and 3rd min of the painful procedure, 7.0, 4 and 4 in infants in KC group vs 15.0, 15.5 and 15.0 ( $p < 0.001$ , $p = 0.001$ , $p = 0.047$ , respectively)

motor activity, and salivary cortisol levels in full-term neonates undergoing heel lance (Nishitani et al., 2009). Infants exposed to mothers' own milk odour had significantly lower scores and values for all outcome measures when compared to controls. There were no significant differences noted in the other groups for any of the outcomes compared to the controls.

### Facilitated tucking

Facilitated tucking consists of a care provider or parent using their hands to provide containment and a supportive boundary to an

infant undergoing a stressful or painful procedure. While typically performed by nurses, it has been used by mothers (Axelin et al., 2006, 2010). The infant is generally held in a side-lying, flexed fetal-type position (Axelin et al., 2006, 2009b; see Holstii et al., Chapter 57, this volume, for a more detailed description of facilitated tucking). Facilitated tucking alone, studied in both preterm and very preterm infants, has been associated with diminished pain scores following heel lance and endotracheal suctioning (Axelin et al., 2006; Ward-Larson et al., 2004) when compared to placebo. Similarly, when used in combination with non-nutritive sucking,

34 preterm infants receiving facilitated tucking during heel lance had significantly lower mean (standard deviation) pain scores during heel-stick procedures (6.39 (3.35) and 7.15 (3.88), respectively) than those receiving routine care (9.52 (4.95)) (Liaw et al., 2012). Facilitated tucking is also more beneficial when compared to oxy-codone (Axelin et al., 2009b). Following endotracheal suctioning, facilitated tucking by parents was equivalent to glucose (Axelin et al., 2009a); however, this was not the case following repeated heel lance. In a study examining preterm infants between 24 and 32 weeks GA randomized to receive facilitated tucking, sucrose or combination of sucrose and facilitated tucking following over time for repeated heel lances, facilitated tucking alone was less effective than sucrose; however, Bernese Pain Scale for Neonates (Cignacco et al., 2004) scores were lowest when combined with the sweet taste (Cignacco et al., 2012).

### Sensorial saturation

Combining strategies, including talking to the infant, massaging or stroking the infant as well as giving a sweet solution, has been coined sensorial saturation by Bellieni and his group (Bellieni et al., 2001, 2002). Typically, sensorial saturation is performed by nursing staff; however, in one study with full-term neonates, mothers did the sensorial saturation (Bellieni et al., 2007). Both mothers doing it for the first time and experienced nurses doing sensorial saturation were more effective than glucose and pacifier, but there were no significant differences between the two. It could be that the experience of the nurses waived differences or it could be that, it did not matter who did the intervention.

### Maternal–infant interactions related to pain experience

As infants develop and have more interactions with their mothers, patterns of interactions become established. Healthy infants who do not experience hospitalization beyond normal nursery care in the first few days of life, are subjected to immunization pain. Mothers, perhaps as a reflection of the stress associated with their infant experiencing pain from an elective procedure, will intuitively apologize, empathize, and give reassurance such as ‘don’t worry’ or ‘it will be okay’ (McMurtry et al., 2010). These actions, have been found to be less effective than distraction approaches that might include singing, offering a toy in reducing both intensity and duration of pain response (Blount et al., 2008, 2009; also see Cohen et al., Chapter 53, this volume). Similar to the effect in preterm neonates, proximal strategies, such as the mother rocking (Campos, 1994) also reduced pain response. Furthermore, controlling for factors such as age, previous pain exposure, medical history, in a sample of 4- and 6-month-old infants, mothers and fathers made more proximal coping promoting behaviours prior to the immunization than health care professionals which significantly decreased facial actions of their infants during the immunization (Piira et al., 2007).

It is perhaps less the specific behaviours that mothers use as opposed to maternal sensitivity to the infant cues that is important. This only becomes strongly associated with decreased pain response as mother and infant have longer time together. For example, in Sweet’s prospective study of 6- and 18-month-old infants undergoing immunization, maternal sensitivity was a significant predictor of lower distress only at the 18-month visit (Sweet et al., 1999). Similarly, Pillai Riddell following a cohort of infants across the first year of life, found that maternal availability/sensitivity was

a significant predictor across all phases of the immunization procedure (Pillai Riddell et al., 2011). Pillai Riddell and colleagues suggested that this ability of the mother to accurately use the infant cues, as well as the infant’s ability to display learned cues resulting in maternal caring response, is directly related to maternal–infant attachment, which typically peaks at 1 year of age (Ainsworth, 1969). For an in-depth discussion on psychological theories and models, see Pillai Riddell et al. (Chapter 9, this volume).

### Other providers

KMC or SSC provides a multisensorial context encompassing tactile, olfactory, and relational systems (Campbell-Yeo et al., 2011). Consistent findings from numerous studies clearly support the comforting role of a mother. What is less known, is whether this comfort relates only to a mother or whether other providers, (e.g. an adult who cares for you or someone familiar) could provide a similar comforting effect. In the first study to address this question, alternate women ( $n = 22$ ), biologically unrelated to the mother, were compared to infants’ own mothers using a cross-over design (Johnston et al., 2012). PIPP scores were lower in the infant’s own mother group (8.3 versus 6.0 at 90 sec post-lance) although this difference was not statistically significant due to the small pilot sample, but effect size was greater than other studies at 90 and 120 sec supporting the effectiveness of the biological mother. Although highly plausible, these findings need to be interpreted with caution due to the small sample size.

Using a similar crossover design, comparison between fathers or mothers who provided KMC for 30 min was made prior to and during heel lance (Johnston et al., 2011). Although PIPP scores were lower in both groups compared to historical controls, mothers provided more analgesic effect and infants recovered faster than when with fathers (mean difference of 1.4 at 30 sec, 1.5 at 60 sec; no difference at 90 sec and 120 sec; time to recover 204 sec versus 246 sec), respectively.

Interestingly, the PIPP scores were very low but not statistically different between preterm twins who were co-bedding (being cared for together in the same incubator allowing skin contact between them) prior and during heel lance and provided sucrose compared to a similar population receiving sucrose alone, considered standard care (SC) in the first minute post heel lance (7.1(SD2.8), 6.1(SD3.0) versus 7.2 (SD3.4), 5.2 (2.0)) (Campbell-Yeo et al., 2012). At 90 sec, PIPP scores were higher in the co-bedding group 6.0 (SD 3.0) compared to 5.0 (SD1.8) ( $p < 0.05$ ), in the SC group. Although higher, the clinical significance of this difference at 90 sec post lance is uncertain. Reasons for the lack of analgesic effect may be due to the lack of full ventral contact and the upright position present during kangaroo care which is not possible during co-bedding. Or, it may be that mother’s ability to effectively provide pain relief is unique. Further research is needed to elucidate these findings. Nevertheless, co-bedding was associated with the twins’ ability to better regulate the pain associated with heel lance. The co-bedding twins recovered more than a minute faster than the SC group, mean time of 75.6 sec, compared to 142.1 sec during SC. Further analysis using generalized estimating equation modelling (GEE) and including corrected GA less than 32 weeks at heel lance did not change these findings and resulted in a  $p$  value of 0.005. Salivary cortisol levels, a reliable biomarker of stress, were significantly lower, mean levels 0.28 mcg/dL (SD 0.25) versus 0.50 mcg/dL (SD 0.73), in the co-bedding twins (see Table 58.2).

**Table 58.2** The effectiveness of maternal- or family-driven non-pharmacological strategies for reduction of procedural pain

Intervention	Gestational age	Procedure	Findings	Effect
Breastfeeding and expressed breast milk (Codipietro et al., 2008; Efe and Ozer, 2007; Gray et al., 2002; Osinaike et al., 2007; Shah et al., 2008)	Full term Preterm	Venepuncture Heel stick	↓ crying time and smaller increase in HR with breastfeeding compared to swaddling ↓ PIPP scores with breastfeeding compared to placebo. Mixed results when comparing breastfeeding to sweet solutions	Breastfeeding is effective; conflicting results regarding expressed breast milk
Kangaroo care (or skin-to-skin contact) (Akcan et al., 2009; Castral et al., 2008; Cong et al., 2009, 2011; de Sousa Freire et al., 2008; Ferber and Makhoul, 2008; Gray et al., 2000; Johnston et al., 2008; Kashaninia et al., 2008; Kostandy et al., 2008; Ludington-Hoe et al., 2005)	Full term Preterm Very preterm	Heel stick Venepuncture Intramuscular injection	↓ crying, less variation in HR ↓ PIPP scores Better results when combined with breastfeeding or sweet taste	Kangaroo care or skin-to-skin care is effective
Containment/facilitated tucking (Axelin et al., 2006, 2009b; Cignacco et al., 2012; Corff et al., 1995; Obeidat et al., 2009; Ward-Larson et al., 2004)	Term Preterm	Endotracheal/ pharyngeal suctioning/ heel Lance	↓ physiological and behavioural pain responses. Less efficacious than sucrose	Containment and swaddling are effective for single procedures. May be optimal as adjuvant strategy for repeated procedures
Auditory recognition: maternal heart rate (Kurihara et al., 1996) recorded maternal voice (Johnston et al., 2007)	Full term Preterm	Heel stick	↓ HR, ↑ oxygenation and quicker recovery Strongest effect combined with NNS	Maternal heart beat effective but not recorded maternal voice
Olfactory recognition: own mother's milk or familiar odour (Goubet et al., 2003, 2007; Nishitani et al., 2009; Rattaz et al., 2005)	Full term Preterm	Heel stick Venepuncture	↓ crying and grimacing during venepuncture	Mothers own milk or familiar odour was effective during venepuncture but not heel lance

HR = heart rate; NNS = non-nutritive sucking; PIPP = Premature Infant Pain Profile.

### Mechanisms underlying maternal comforting effectiveness

There are likely several underlying mechanisms for the effectiveness of maternal comfort on infant pain. The two mechanisms with the most compelling data related to endogenous opiates and oxytocin.

In the animal literature, there is a strong relationship between endogenous opiates and social affiliation (Panksepp et al., 1980, 1994), including mother–infant bonding. Endorphins are excreted in milk and the levels are augmented by suckling. Young animals, of several species, removed from their mothers display distress behaviours including specific crying, or distress vocalizations. When given opiates exogenously, the number of these distress behaviours decrease, as when they are reunited with the mother. Furthermore, naloxone, in many experiments, though not all, decreases the number of distress vocalizations when the young are separated. There is congruence of areas in the brain responsible for distress behaviours and opiate receptors. The important point is that the behaviours and the opiate excretion are mediated by maternal presence. The opiate-affiliative system is also bi-directional: dams (mother rats) given naloxone are slower to retrieve their young scattered about the nest.

The second hypothesized mechanism is related to oxytocin. Oxytocin is thought to be of major importance in mother–infant bonding; being released at delivery, with the commencement of suckling, with touch, and is found in breast milk (Carter, 1998;

Carter et al., 1992; Insel, 1997; Konner, 2004). The role of oxytocin in the mediation of pain has been tested in animals. Based on the knowledge that gentle stroking has a pleasurable anti-nociceptive function, the injection of an oxytocin antagonist blocked that function (Agren et al., 1995). Further studies revealed that: (1) stroking did increase the latency withdrawal to mechanical or thermal noxious stimulation; (2) there were increased levels of circulating oxytocin and oxytocin in the periaqueductal grey (PAG), an area important in pain processing, following stroking sessions; and (3) an *opiate* antagonist, naloxone, injected directly into the PAG, decreased the withdrawal latency. In adults, the administration of oxytocin has decreased pain (Madrado et al., 1987; Yang, 1994).

### Recommendations for practice

Given the current evidence regarding the comforting role of mothers and families in the NICU and the lack of reported adverse events, we recommend that for healthy full-term and preterm infants, KMC and breastfeeding should be considered as the behavioural pain strategy of choice for single painful events. Where possible, breastfeeding infants should establish an effective latch prior to the procedure and have as much direct skin contact with the mother as possible.

In infants who are unable to breastfeed, KMC is beneficial. Infants should be placed diaper clad in an upright position with full ventral contact with their mother prior to and during the painful procedure. The optimal duration of SSC prior to a procedure remains

unknown. The majority of studies used 15 to 30 min and had positive results, and as little as 10 min seems to be effective.

In the situations where it is impossible to hold the infant, alternative strategies emphasising maternal presence such as olfactory or auditory stimuli, or facilitated tucking may be used as adjuvant therapy in conjunction with sweet taste or in combination as more holistic sensorial saturation. Further studies are required to determine the efficacy of these strategies for repeated procedures over time.

Some benefit is derived from KMC with other providers who are not the mother; however, until further studies are conducted, additional strategies in combination should be considered. For infants undergoing multiple painful procedures or those who demonstrate high behavioural pain response, adjuvant strategies used in combination specifically sweet taste, non-nutritive sucking, swaddling or containment in addition to breastfeeding or SSC are likely to be beneficial, although there remains a paucity of evidence regarding an optimal combination.

### Feasibility

Some outstanding issues remain regarding the implementation of KMC during painful procedures. We know that the uptake of any clinical practice change generally lags behind dissemination of the research findings (Graham et al., 2006; also see Yamada and Hutchinson, Chapter 61, this volume). Using mothers and families as providers of comfort presents several additional challenges, requiring a paradigm shift. Health care providers will need to further relinquish their traditional care model to consider parents as partners in provision of care rather than bystanders; thus placing increased emphasis and time for the coordination of care, scheduling, and timing of procedures to enhance parental involvement. The skill of the health care providers conducting the procedure also needs to be considered in relation to feasibility. Issues regarding safety and ergonomic needs of the care providers have also been reported (Campbell-Yeo et al., 2008b) and require further research.

### Conclusion

Mothers have a unique relationship with their infant and a special role in comforting their infant in the face of pain. Data exist to support that mothers are better than others at comforting their infant, either through some biological mechanism or because of the profound caring they have for their infant, normally stronger than others. Given their effectiveness, it is highly recommended that mothers be included in comforting their infant during painful procedures whenever possible.

#### Case example

Madeline is a 7-day-old preterm neonate who was delivered 11 weeks early at 29 weeks gestational age. Madeline undergoes numerous painful procedures, as part of her medical care in the NICU. For example, heel lance for blood collection, the most common, occurs one to two times a day.

Madeline becomes very distressed during the heel lance as exhibited by her facial actions and changes in her physiological stability. She often requires additional supplemental oxygen during the heel lance.

Madeline's mother, Sarah, also becomes visibly upset when she watches during these procedures and describes, 'feeling helpless'. Madeline's nurse discusses the comforting benefits of SSC with Sarah and asks if she would like to hold Madeline in this way before and during her next heel lance. Sarah agrees and her nurse tells explains to her this would mean holding Madeline, while her baby wears only a diaper, and placing her upright in a ventral position on her bare chest, than covering them both with a blanket (for an example see Figure 58.1). The nurse also told her that even a small amount of SSC before the heel lance can be helpful, as little as 10 to 15 min, but that it is important to allow Madeline to recover from the transfer from the incubator to her mother's chest which may take a few extra minutes.

The next day, Sarah held Madeline in SSC during her heel lance. Sarah displayed only minimal facial response during the procedure and did not require additional oxygen. Both the nurse and Sarah felt that Madeline benefited from the SSC. Sarah also expressed that she 'truly felt like a parent since she was able to actively help her daughter' that she 'would like to be able to continue helping Madeleine in this way'.

The nurse shares with the neonatal team that Sarah would like to be an active participant in Madeleine's pain management and the team agrees that all non-emergent blood collections and procedures can be scheduled around Sarah's availability.

Figure 58.1 Skin-to-skin contact during a heel lance.

## CHAPTER 59

---

# Complementary drugs—herbs, vitamins, and dietary supplements for pain and symptom management

Joy A. Weydert

### Summary

Because of the interest of patients and physicians, there has been increasing research into the use of botanical agents, nutritional supplements, and diet as a means to manage pain. Pharmacological agents typically are chosen as first-line therapy for pain and symptom management; however, for some patients these agents may not work well long term or have side effects that are not tolerated. Other patients may prefer non-pharmacological therapies. Most clinicians are not trained or may not be comfortable recommending these complementary agents.

### Introduction and background

The use of complementary and alternative medicine (CAM) has increased considerably in the paediatric population (Tsao and Zeltzer, 2005). Approximately 20% to 40% of healthy children seen in paediatric clinics and more than 50% of children with chronic illnesses use CAM in conjunction with conventional medical care (Kemper et al., 2008). Those groups that report higher use of CAM often have chronic disorders in which pain is a significant problem (Hagen et al., 2003; Heuschkel et al., 2002).

Families who use CAM state they do so ‘not so much as a result of being dissatisfied with conventional medicine, but largely because they found these health care alternatives to be more congruent with their own values, beliefs, and philosophical orientations toward health and life’ (Astin, 1998, p. 1548).

The National Center on Complementary and Alternative Medicine (NCCAM), a division of the National Institutes of Health (NIH), funds various studies on CAM. Research on the effectiveness of various CAM therapies for children is small but growing. Much of our knowledge of these therapies is extracted from adult studies, however paediatric studies will be reviewed in this chapter when available.

The herbs that will be discussed have ‘Generally Recognized As Safe’ status (GRAS) for use in the US. GRAS is the US Food and Drug Administration (FDA) designation that a chemical or substance is considered safe by experts, and so exempted from the usual Federal Food, Drug, and Cosmetic Act (FFDCA) food additive tolerance requirements. GRAS exemptions are granted for substances that are generally recognized, among experts qualified by scientific training and experience to evaluate their safety, as having been adequately shown through scientific procedures to be safe under the conditions of their intended use (Food and Drug Administration, 2012). Common dosages of herbs, vitamins, and dietary supplements are shown in Table 59.1.

### Pain syndromes and suggested complementary drugs

#### Headaches

Chronic primary headaches, whether tension-type or migraine, are the most common pain problems in children affecting as many as one in five children (Perquin et al., 2000). Recent theories of headache aetiology increasingly point to similarities between migraine and tension-type headache, with both suggesting an underlying heightened central nervous system sensitivity (Peres et al., 2007). The goal for treatment, therefore, is to target the underlying problem within the nervous system to lessen reactivity.

#### Magnesium

Magnesium is regarded as a natural muscle relaxant and pain reliever. Its mechanism of action is through antagonizing N-type calcium-mediated channels at nerve endings. This prevents noradrenaline release, thereby depressing nerve transmission and muscle contractility (Shimosawa et al., 2004). Magnesium also has voltage-gated antagonist action at the N-methyl-D-aspartate

**Table 59.1** Common dosages of herbs, vitamins, dietary supplements—please refer to text for more details on dosing, side effects, interactions

Butterbur	50–100 mg two to three times a day
Chamomile	1–3 g three to four times a day
Coenzyme Q <sub>10</sub>	100–300 mg a day
Digestive enzymes	1 capsule before meals (25:2:25 ratio of amylase:lipase:protease)
Feverfew	50–150 mg a day
Ginger	250–500 mg three times a day
L-Carnitine	1000–2000 mg in divided doses three times a day
L-Theanine	100–200 mg one to two times a day
L-Tryptophan/5-HTP	50–300 mg a day
Lemon balm	100–200 mg three times a day
Magnesium	250–500 mg twice a day
Marshmallow	2–5 g three to four times a day
Melatonin	0.3–5 mg 30 min before bedtime
Peppermint (enteric coated)	200–400 mg three times a day
Probiotics	10–100 billion CFU one to two times a day
Slippery elm	400–500 mg 3–4 times daily
Valerian	100–300 mg before bedtime
Vitamin B complex	One tablet a day
Vitamin D <sub>3</sub>	1000–4000 IU a day

(NMDA) receptors preventing excessive neuronal depolarization (Sun et al., 2005). Deficiencies in magnesium play an important role in the pathogenesis of migraine headaches by promoting cortical spreading depression, altering neurotransmitter release, promoting hyperaggregation of platelets, and causing vasoconstriction, all of which are relevant features of our current understanding of migraine pathophysiology. Magnesium deficiency also results in the generation and release of substance P, which is believed to act on sensory fibres and produce headache pain (Sun-Edelstein and Mauskop, 2009).

There have been conflicting reports in the literature regarding the actual magnesium levels in relation to reports of headache pain. Only 1% of the total body magnesium is in the measurable extracellular space, therefore the levels found on routine blood testing do not reflect total body stores. It is the serum ionized magnesium level (IMg<sup>2+</sup>) that truly reflects disturbed magnesium metabolism. Patients who have low IMg<sup>2+</sup> may have normal serum levels, therefore, IMg<sup>2+</sup> levels provide more consistent and reliable results (Altura et al., 1992). Normal IMg<sup>2+</sup> for children ranges from 1.09 to 1.51 mg/dL and typically does not vary with age (Hoshino et al., 1998). Levels of red blood cell (RBC) magnesium have also been shown to be decreased in migraineurs (Gallai et al., 1993) as well as in juvenile migraine patients with and without aura (Soriani et al., 1995). Given its commercial availability, the RBC magnesium assay may be a better way of assessing for

deficiency. Normal RBC magnesium levels for children are 4.7 to 7.0 mg/dL.

In one study, 86 children between the ages of 3 and 17 years with migraine headaches were randomly assigned to receive magnesium or placebo for 16 weeks to prevent headache pain. Baseline mean IMg<sup>2+</sup> levels in both treatment and placebo groups were similar at 0.5 and 0.49 mg/dL, respectively. There was a significant reduction in both headache frequency ( $p = 0.0037$ ) and severity ( $p = 0.0029$ ) in the children taking magnesium oxide (9 mg elemental Mg<sup>2+</sup>/kg/day) compared with those who took the placebo. The only reported side effect was loose stools—19% in magnesium oxide group and 7% in the placebo group (Wang et al., 2003). Oral magnesium supplementation has also been found to decrease pain in children due to tension-type headache (Grazzi et al., 2007). Twenty-two patients were given magnesium pidolate 2.25 g twice a day for 3 months. There was significant reduction in number of headache days (69.6% improvement,  $p = 0.001$ ), analgesic consumption (65.4% improvement,  $p = 0.0001$ ), and Migraine Disability Assessment scale (MIDAS) score (75.5% improvement,  $p = 0.001$ ) at 12 months compared to baseline. The treatment was well tolerated and free from serious side effects.

Acute treatment with intravenous magnesium has been used in adults to abort headache pain in an outpatient clinic setting (Demirkaya et al., 2001; Mauskop et al., 1996). Of 40 patients given intravenous (IV) infusion of 1 g of magnesium sulphate, 80% had complete elimination of pain within 15 min of infusion ( $P < 0.001$ ). They also had complete elimination of photophobia, phonophobia, and nausea for 24 h (Mauskop et al., 1996). These patients subsequently were found to have low serum IMg<sup>2+</sup> levels. There are no clinical trials using IV magnesium acutely to terminate migraine in children.

Oral magnesium's efficacy is dependent on its absorption from the gastrointestinal tract. Magnesium oxide is poorly absorbed and can cause diarrhoea. Use of the magnesium salts glycinate, aspartate, gluconate, citrate, malate, will yield better results without causing diarrhoea (Ranade and Somberg, 2001). Typical dosing for children is 250 to 500 mg orally twice a day—start with the lower dose and gradually increase the dose for effect. For acute management of migraine in a hospital or emergency department setting, 1 g of magnesium sulphate can be given IV over 15 min in patients with normal cardiovascular and renal function.

**Vitamin B complex**

Mitochondrial function has been found to be impaired in migraine patients (Gaby, 2011; Pieczenik and Neustad, 2007) and may be related to the B vitamins thiamin (B<sub>1</sub>), riboflavin (B<sub>2</sub>), niacin (B<sub>3</sub>), pantothenic acid (B<sub>5</sub>), pyridoxine (B<sub>6</sub>), and biotin which are needed in mitochondrial energy production through synthesis of coenzyme A, transfer of amino groups, donation of methyl groups, and activation of other enzymes. In addition, elevated homocysteine levels and lower serum and red blood cell folate levels are seen in both adult and paediatric patients with migraines (Nelson et al., 2010; Oterino et al., 2010). Homocysteine accumulation leads to impaired fatty acid synthesis, inflammation, vascular damage, and nervous system dysfunction. Other B vitamins (folic acid, cobalamin (B<sub>12</sub>), pyridoxine (B<sub>6</sub>), and pantothenic acid (B<sub>5</sub>)) may play a role in mitigating migraine headache by lowering homocysteine levels. Vitamin B<sub>6</sub>, 100 mg given twice a day, doubled RBC magnesium levels after 4 weeks of therapy in pre-menopausal women

(Abraham et al., 1981) so could have effects in treating migraine through this mechanism as well.

Studies in children using single supplementation of riboflavin ( $B_2$ ) at doses 50 to 200 mg have been equivocal (Bruijn et al., 2010; MacLennan et al., 2008). However, a retrospective study of 41 children given riboflavin 200 to 400 mg daily found a significant reduction in both migraine frequency and intensity (Condò et al., 2009).

In another study of 16 paediatric patients with migraine, hyperhomocysteinaemia, and methylenetetrahydrofolate reductase (MTHFR) polymorphisms, ten out of 16 patients had complete resolution of the migraine episodes using folic acid 5 mg daily for 6 months. The plasma levels of homocysteine dropped to the normal range in 100% of patients (Di Rosa et al., 2007).

Adult studies have shown efficacy in using sustained release niacin ( $B_3$ ) 375 mg twice a day or vitamin  $B_{12}$ , either 1 mg intranasally daily or 1000 mcg intramuscularly every week, but these studies have not been done in children or adolescents (van der Kuy et al., 2002).

It is unlikely that any individual would have a single vitamin B deficiency. Various B vitamins share similar but not identical functions, therefore, supplementation with a daily B-50 complex formulation could be used when treating headache in children. This would provide 50 mg of vitamins  $B_1$ ,  $B_2$ ,  $B_3$ ,  $B_5$ ,  $B_6$ ; 50 mcg of cobalamin and biotin; and 400 mcg of folic acid. All B vitamins are water-soluble, so excess amounts are readily excreted by the kidneys rather than accumulate in fatty tissue which can occur with fat-soluble vitamins—A, D, E, K.

### Vitamin D—cholecalciferol (vitamin $D_3$ )

Very low vitamin D levels have been found in a survey of children with migraine (O'Brien et al., 2010). Vitamin D deficiency is associated with higher levels of pro-inflammatory and pro-coagulatory biomarkers—high sensitivity C-reactive protein, homocysteine, tissue plasminogen activator antigen, and von Willebrand factor. These same biomarkers are known to be elevated in adult and paediatric patients with migraine indicative of endothelial activation and vascular reactivity caused by inflammation and oxidative stress (Nelson et al., 2010; Tietjen et al., 2009). Vitamin D, important for neurovascular stability, immune modulation, and antithrombotic effects which lessen cardiovascular and stroke risks, is likely important, too, in decreasing the incidence of migraine.

Thus far no randomized, placebo controlled studies have been conducted using vitamin D however several case reports suggest that vitamin D may indeed be effective in reducing pain in migraines and related conditions in adults. Vitamin D and calcium supplementation were used to successfully treat premenopausal and postmenopausal women with migraines who previously did not get relief with conventional therapies (Thys-Jacobs, 1994a, 1994b). Other case reports also demonstrated reduction of headache pain with vitamin D (1000–1500 IU) and calcium (1000–1500 mg) supplementation within 4 to 6 weeks. Though the role of calcium in suppressing these headaches could not be ruled out, they surmised that vitamin D was more vital for headache relief in that serum calcium levels normalized within the first week of therapy, but headache pain only abated with normalization of the 25-hydroxy vitamin D (25(OH)D) levels at 4 to 6 weeks of treatment (Prakash and Shah, 2009).

For patients with migraine or tension headaches, target a serum 25(OH) D level of 50 to 60 ng/ml. Many children may need higher

than the current AAP recommendation of 400 IU daily as 100 IU of vitamin  $D_3$  only raises the serum level by 1 ng/ml. It is safe to give 2000 to 4000 IU daily if levels are monitored every 6 to 8 weeks. Symptoms of vitamin D toxicity (levels >150 ng/ml) might include nausea, vomiting, poor appetite, weakness, confusion, or tingling around the mouth, and are related to hypercalcaemia and hypercalciuria. Published cases of toxicity revealed intake of greater than 40 000 IU per day (Vieth, 1999).

### Butterbur (*Petasites hybridus*)

Butterbur is a perennial shrub that historically has been used to treat migraine, allergic rhinitis, chronic cough, and urinary tract spasms. The active constituents of butterbur, petasin and isopetasin, have antispasmodic effects on smooth muscle and vascular walls by non-competitive inhibition of histamine (Ko et al., 2001). They also inhibit leukotriene synthesis, and decrease the priming of mast cells, which lowers the concentration of histamine *in vitro* (Lee et al., 2003). Histamine is a key component of the neuroinflammatory process contributing to migraine acting mainly on H1 receptors which mediate inflammation and H3 receptors which serve as negative feedback to inhibit further excessive release of histamine by C-fibres (Gupta et al., 2011). Butterbur thereby impacts migraine pain via these mechanisms.

Butterbur contains hepatotoxic pyrrolizidine alkaloids (PAs) which are most concentrated in the plant roots, but may be found in all plant parts. Toxic PAs are removed from butterbur extracts. These PA-free extracts are available for use and are considered safe.

Butterbur root extract was found to be an effective and well-tolerated migraine prophylaxis for children and teenagers (Pothmann and Danesch, 2005). 108 children and adolescents between the ages of 6 and 17 were included in a multicenter prospective open-label study of butterbur. Children 6 to 9 years of age initially received 50 mg of the butterbur extract once a day and adolescents aged 10 to 17 years received 50 mg twice a day. After 2 months the dose for non-responders increased to 75 mg daily (6–9-year-olds) or 75 mg twice a day (10–17-year-olds). The number of monthly migraine attacks was reduced 63.2% for the total sample population at the end of 4 months in relation to pre-study baseline measures and the duration of pain was reduced, on average, from 10 h to 7 h. No serious adverse events occurred.

For migraine headache prophylaxis, a PA-free butterbur rhizome extract standardized to 15% petasin and isopetasin (Petadolex®) can be used in doses of 50 to 100 mg twice daily with meals. Three times daily dosing has been used in children who don't respond to the twice daily dose. The most commonly reported adverse events related to butterbur were belching, drowsiness, fatigue, nausea, and abdominal pain. These adverse events are generally considered mild and self-limiting.

### Feverfew (*Tanacetum parthenium*)

Feverfew traditionally has been used for the prevention and treatment of migraine headaches, arthritis, fever and menstrual irregularities. Feverfew inhibits platelet aggregation, serotonin release from platelets and leukocytes, and the production of prostaglandins and leukotrienes in rat and human leukocytes (Sumner et al., 1992). It also has serotonin 5-HT receptor blocking effects which has relevance as serotonin dysregulation is thought to contribute to headache initiation (Shrivastava et al., 2006). One of the major active constituents in feverfew, parthenolide, inhibits the influx

of extracellular calcium into vascular smooth muscle cells decreasing spasm (Pareek et al., 2011).

Randomized trials of feverfew in adult patients reduced the number and severity of migraine attacks when used singularly (Murphy et al., 1988) or in combination with ginger (Cady et al., 2011). In the 1988 study, 72 volunteers were randomly allocated to receive either dried feverfew leaves (82 mg/day) or matching placebo for 4 months with cross-over for the following 4 months. Feverfew treatment had a 24% reduction ( $P < 0.005$ ) in attack frequency and a significant decrease ( $P < 0.02$ ) in migraine-associated nausea and vomiting compared with placebo. Visual analogue scale (VAS) scores of pain also improved with feverfew.

There have been no trials of feverfew in any paediatric populations, although it is frequently recommended for paediatric headache management. No significant adverse effects have been reported with long-term use of feverfew (Pittler et al., 2000). The recommended dosing is 50 to 150 mg of feverfew extract standardized to 0.2% to 0.4% parthenolides, or two to three fresh leaves daily. Use the 50 mg dose for children 25 to 50 kg and the 150 mg dose for larger children and adults ( $>70$  kg).

### Coenzyme Q<sub>10</sub> (CoQ<sub>10</sub>)

CoQ<sub>10</sub> deficiency occurs in many paediatric patients with migraine headache (Hershey et al., 2007). There are two major factors that lead to deficiency of CoQ<sub>10</sub> in humans: reduced biosynthesis and increased utilization by the body when consumed by oxygen free-radicals. Oxidative stress (indicated by low CoQ<sub>10</sub> levels) with mitochondrial dysfunction (indicated by low ATP levels in blood mononuclear cells) are found in pain disorders such as migraine and fibromyalgia (Cordero et al., 2012). CoQ<sub>10</sub> functions as an anti-oxidant, a membrane stabilizer, as well as a co-factor in many metabolic pathways, and is necessary for generating ATP in mitochondrial oxidative respiration (Turunen et al., 2004).

CoQ<sub>10</sub> supplementation reduced headache frequency and related disability in children with migraine when CoQ<sub>10</sub> blood levels were normalized. CoQ<sub>10</sub> was measured in 1550 paediatric patients, aged 3 to 22 years, with migraine. Patients with low CoQ<sub>10</sub> ( $<0.70$  mcg/ml; normal levels 0.5–1.5 mcg/ml), were started on 1 to 3 mg/kg per day of CoQ<sub>10</sub> in liquid gel capsule formulation. In 3 months, the total CoQ<sub>10</sub> level improved to  $1.20 \pm 0.59$  mcg/ml ( $P < 0.0001$ ), while the headache frequency decreased from  $19.2 \pm 10.0$  to  $12.5 \pm 10.8$  ( $P < 0.001$ ) and headache disability assessed with PedMIDAS reduced from  $47.4 \pm 50.6$  to  $22.8 \pm 30.6$  ( $P < 0.001$ ) (Hershey et al., 2007).

CoQ<sub>10</sub> is generally well tolerated and has no significant adverse effects. Small amounts are derived from dietary meats and seafood; however, the amounts ingested from foods do not approach therapeutic doses. The recommended dosing when used for migraine prevention is 100 to 300 mg daily.

### Functional abdominal pain/inflammatory bowel disease

The causes of functional abdominal pain are multifactorial and often difficult to treat with only one modality. Change of diet, cognitive-behavioural therapy, and use self-regulation techniques (guided imagery, hypnosis, meditation) used concurrently can help relieve pain (Weydert, 2012). Along with these modalities, certain herbs and dietary supplements have been shown to be safe and effective in treating abdominal pain. Many of these same supplements can

also be integrated into the regimens for inflammatory bowel disease (IBD) to quell inflammation and subsequently reduce pain.

### Chamomile (*Matricaria recutita*)

Chamomile traditionally has been used to treat nausea, nervous diarrhoea, gastrointestinal spasms, restlessness and insomnia. Active ingredients, alpha-bisabolol and bisabolol oxide, inhibit cyclo-oxygenase and lipo-oxygenase thereby reducing the production of inflammatory prostaglandins and leukotrienes. They also inhibit histamine release from mast cells and have antispasmodic effects on smooth muscle (Hormann and Korting, 1994). Another active ingredient, apigenin, binds to gamma-aminobutyric acid (GABA) receptors, the primary receptor sites of benzodiazepines in the central nervous system, to exert anxiolytic effects without sedation (Viola et al., 1995). In a prospective double-blind study in 33 infants with colic, an herbal preparation containing chamomile was effective in reducing colic episodes without side effects. The tea eliminated the colic in 19 (57%) of 33 infants, whereas placebo was helpful in only 9 (26%) of 35 ( $P < 0.01$ ) (Weizman et al., 1993).

One heaping teaspoon of dried flower heads in half a cup of boiling water steeped for 10 min yields about 3 g of chamomile extract. For infants with colic, give 1 ounce of this preparation (approximately 0.75 g) three to four times daily. Use higher doses for older children and adolescents—1 to 3 g taken three to four times daily—to reduce abdominal and/or menstrual cramps, or induce relaxation.

### Ginger (*Zingiber officinale*)

Historically ginger has been used for stomach aches, headaches, nausea, and to stimulate appetite, reduce gas formation, and promote bile secretion for digestion. Its active constituent, 6-gingerol, reduces nausea and vomiting by increasing gastric motility (Ali et al., 2007). Ginger's antispasmodic effect on the visceral smooth muscle is the result of antagonism of serotonin receptor sites in the gastrointestinal tract (Murray, 1995). Twenty-four healthy volunteers were studied twice in a randomized double-blind manner and given ginger capsules (total 1200 mg) or placebo followed by a soup meal. Ginger accelerated gastric emptying ( $13.1 \pm 1.1$  versus  $26.7 \pm 3.1$  min,  $P < 0.01$ ) and stimulated antral contractions ( $P < 0.005$ ) compared to placebo (Wu et al., 2008).

Ginger is well tolerated and considered safe when used in typical doses in children older than 2 years old. Ginger can be given by brewing 0.5–1 g of dried root in 150 ml boiling water for 5–10 min, then straining. Powered root in capsule form can also be used and dosed 250–500 mg 3–4 times daily up to the maximum of 4 g per day. It is generally recommended that intake not exceed 4 g per day in adults as side effects such as abdominal discomfort, heartburn, or diarrhoea may develop with doses greater than 5 g per day (Srivastava and Mustafa, 1989).

### Peppermint (*Mentha piperita*)

There are over 40 different compounds found in peppermint oil. Most research has focused on menthol which decreases the influx of extracellular calcium ions through potential-dependent channels thus inhibiting smooth muscle contractions (Hills and Aaronson, 1991).

In a randomized, double-blind controlled trial, 42 children aged 8 to 17 years with irritable bowel syndrome (IBS) were given pH-dependent, enteric-coated capsules containing 187 mg of peppermint oil per capsule or placebo. Children weighing

between 30 and 45 kg received one capsule three times a day whereas patients weighing more than 45 kg received two peppermint oil or placebo capsules three times a day. After 2 weeks, 75% of patients receiving peppermint oil had reduced severity of pain compared to only 19% of the placebo group ( $P < 0.001$ ) (Kline et al., 2001).

Peppermint is widely used as a tea. Due to its effect on calcium channels it can cause relaxation of the lower oesophageal sphincter leading to heartburn. Use of the enteric coated capsules will prevent this side effect. Typical dosage of the enteric coated capsules is 200 to 400 mg three times a day.

### Slippery elm (*Ulmus fulva*)

Slippery elm inner bark, from the slippery elm or red elm tree native to North America, is known to soothe inflammation of the gastrointestinal tract. Slippery elm has demulcent and anti-oxidant properties that can protect the gastrointestinal tract from irritation. When taken internally, slippery elm causes reflex stimulation of the goblet cell nerve endings in the gastrointestinal tract producing extra mucous (Natural Medicine Comprehensive Database, 2012). It is popular among IBD patients in the UK (Langmead et al., 2000).

Significant improvement in IBS symptoms were noted with use of slippery elm. Thirty-one subjects received daily formulations of slippery elm. Twenty-one were classified as suffering from diarrhoea-predominant (DA) or alternating bowel habit IBS, and ten classified as constipation-predominant (C) IBS. In the DA group, abdominal pain scores decreased by 19% ( $P = 0.006$ ), bloating scores decreased by 28% ( $P < 0.0001$ ), and global IBS symptoms decreased 21% ( $P = 0.002$ ) during the treatment period. In the C group, there was a 14% decrease in abdominal pain scores ( $P = 0.032$ ), a 13% decrease in bloating severity ( $P = 0.034$ ), and a 34% reduction in global IBS symptom severity ( $P = 0.0005$ ) when mean baseline scores were compared to mean scores over the treatment period (Hawrelak and Myers, 2010).

A tea can be made with adding one tablespoon of powdered inner bark to one cup of boiling water for 15 min. Use 2 to 5 ml three times a day. Capsules: 250–500 mg three to four times daily. Whole bark should not be used as it is considered an abortifacient.

### Marshmallow (*Althaea officinalis*)

Marshmallow is used commonly for inflammation of the gastric mucosa, peptic ulcers, respiratory tract mucous membrane inflammation, and dry cough. Marshmallow leaf and root contain mucilage polysaccharides that form a protective layer to shield mucous membranes from local irritation. The mucilage also has antimicrobial, antispasmodic, antisecretory, and wound-healing effects (Newall et al., 1996).

The leaf tea is prepared by steeping one to two teaspoons of the dried leaf in 150 ml boiling water for 5 to 10 min and then straining. The root tea is prepared by steeping one to two teaspoons of the dried root in 150 ml cold water for 1 to 1½ h, straining, and then warming before consumption (Natural Medicine Comprehensive Database, 2012). Each preparation yields 2 to 5 g to be taken three to four times a day.

### Probiotics

The human intestinal tract is populated with various microbial species that are non-pathogenic but necessary for metabolizing foods and certain drugs, absorbing nutrients, and preventing colonization by pathogenic bacteria. Probiotics produce butyrate, a short-chain

fatty acid important for the health of colonocytes, particularly the epithelial cells in the rectum and left colon. Probiotics activate regulatory T cells and regulatory pathways, leading to down regulation of inflammation (Sartor, 2011).

Two recent double-blind randomized placebo-controlled trials found different types of probiotics (*Lactobacillus* GG and VSL#3®—a commercial brand containing eight different strains) reduced both the frequency and intensity of pain in children with recurrent abdominal pain/IBS (Francavilla et al., 2010; Guandalini et al., 2010). In the Francavilla study, 141 children with IBS or functional pain received either oral LGG ( $3 \times 10^9$  colony-forming units) or oral placebo twice per day. The number of episodes of pain per week decreased in the probiotic group from 3.7 to 1.1 ( $P < 0.01$ ) at 12 weeks, and to 0.9 at week 20 ( $P < 0.02$ ). Pain severity decreased from 4.3 to 2.3 at week 12 ( $P < 0.01$ ) and to 0.9 at week 20 ( $P < 0.001$ ). These decreases were not seen in the placebo group.

Typical dose is 10 to 100 billion colony forming units (CFU) once or twice daily. These preparations can be of a single strain (*Lactobacillus* GG, *Saccharomyces*, etc.) or made of multiple strains combined to treat both small and large intestines.

### Digestive enzymes

Digestive enzymes, amylase, lipase, protease and others, are necessary to facilitate proper breakdown of foods for utilization in our bodies. Incomplete digestion of food in the gastrointestinal tract leads to gas formation, bloating, abdominal cramps and diarrhoea, and food allergies/sensitivities. Chronic hyposecretion of these enzymes not only causes maldigestion, but also malabsorption of micronutrients leading to deficiencies and increased intestinal permeability. Impaired gastric acid and pancreatic function has been reported in Crohn's disease contributing to malnutrition (Winter et al., 2004). These may also help for rehabilitation of the malnourished patient with IBD.

In one study, administration of a digestive enzyme product significantly reduced the bloating, flatulence, and abdominal pain, with a slight increase of urgency for bowel movements in patients with IBS (Ciacci et al., 2011).

A trial of a broad-spectrum digestive enzyme consisting of a ratio of 25:2:25 of amylase:lipase:protease USP units respectively, given with meals may be of benefit in those with the described symptoms. Gradually increase to the dosage recommended by the manufacturer dependant on strength.

### Fibromyalgia/widespread myofascial pain

Patients with fibromyalgia (FM) frequently have musculoskeletal pain, fatigue, headache, anxiety, weakness, and IBS amongst other symptoms. Many of these symptoms can be treated with the use of herbs and dietary supplements while the underlying dysfunction is addressed for long-lasting relief.

### Vitamin D—cholecalciferol (vitamin D<sub>3</sub>)

Vitamin D deficiency is frequently seen in patients diagnosed as FM and non-specific musculoskeletal pain (Bhatti et al., 2010). Vitamin D deficiency causes muscle pain and proximal muscle weakness with reports of heaviness in the legs, rapid fatigue, and problems with climbing stairs and mobility. Vitamin D seems to increase muscle protein synthesis, possibly by activating second messengers and phosphorylation (Pfeifer et al., 2002). In paediatrics, vitamin D deficiency can present as atypical muscular pain.

The child at risk of this is typically white, breastfed, protected from the sun, and obese (Clarke and Page, 2012).

Several case reports suggest vitamin D therapy can provide prompt relief of muscle weakness and restore mobility (Prabhala et al., 2000). In a study of 61 women with FM and 25-hydroxy-vitamin D (25(OH) D) levels <20 ng/ml, significant improvement was noted when their blood level of 25(OH) D became greater than or equal to 30 ng/ml. This improvement became more significant when their blood level of 25(OH) D exceeded 50 ng/ml (Matthana, 2011).

After measuring 25(OH) D levels, dose oral vitamin D<sub>3</sub> to target a level of 50 to 60 ng/ml. Knowing that each 100 IU only raises the 25(OH) D level by 1 IU, doses of 2000 to 4000 IU may be needed to increase levels 20 to 40 ng/ml. Very few foods naturally contain vitamin D. Dietary sources include fortified eggs, fatty fish such as herrings, mackerel, sardines, and tuna, and some fortified foods, though these are minor sources overall.

### Magnesium

As mentioned previously, magnesium is a natural muscle relaxant and pain reliever which achieves its mechanism of action by antagonizing primarily N-type calcium-mediated channels at nerve endings, reducing noradrenaline release, thereby depressing nerve transmission and muscle contractility (Shimosawa et al., 2004). It is also a cofactor driving many enzymatic reactions necessary for mitochondrial function and energy production.

Serum and RBC magnesium levels were significantly lower in patients with FM than in controls with a negative correlation between the magnesium levels and FM symptoms (Bagis et al., 2013). Supplemental magnesium has been used in its various salt forms to treat myalgias. Oral magnesium citrate treatment, 300 mg a day, was effective in reducing tender points and pain intensity of FM (Bagis et al., 2013). It was also helpful in reducing pain and tenderness in adult FM patients when taken orally as magnesium hydroxide with malic acid (Russell et al., 1995).

Typical dosing is 250 to 500 mg orally twice a day. Dietary sources of magnesium include legumes, whole grains, vegetables, seeds, and nuts, though it is difficult to get adequate amounts daily from food alone. Magnesium's efficacy is dependent on its absorption from the gastrointestinal tract. Supplement with magnesium salts, glycinate, aspartate, gluconate, citrate, or malate to promote absorption without causing diarrhoea which can occur with magnesium oxide. Epsom salts, which are 100% magnesium sulphate, can also be used as a compress or a bath soak to relieve muscle pain.

### Vitamin B complex

Many of the B vitamins are cofactors in the Krebs cycle. They serve as facilitators of specific biochemical reactions, i.e. niacin→nicotinamide dinucleotide (NAD), riboflavin→flavin-adenine-dinucleotide (FAD), and therefore necessary for mitochondrial energy production. Deficiencies cause deficits of ATP leading to fatigue, reduce glutathione and nitric oxide synthesis leading to myalgias, and reduce serotonin production causing pain and mood disturbances (Eisinger, 1998).

A number of similarities exist between FM and thiamin deficiency. They include irritability, frequent headaches, unusual fatigue, muscle tenderness, muscular weakness, IBS, and sleep disturbances. Studies have demonstrated abnormalities of thiamin metabolism in FM with increased pyruvate, decreased

lactate production and decreased adenosine triphosphate (ATP) (Eisinger, 1994).

Rather than supplement with separate B vitamins, it would be more effective to supplement with daily B-50 complex formulation which would provide 50 mg of vitamins B<sub>1</sub>, -2, -3, -5, -6; 50 mcg of cobalamin and biotin; and 400 mcg of folic acid.

### Coenzyme Q<sub>10</sub>

CoQ<sub>10</sub> deficiency, mitochondrial dysfunction, oxidative stress, and mitophagy activation in blood mononuclear cells have been observed in FM patients. CoQ<sub>10</sub> transfers electrons in the mitochondrial respiratory chain and fulfils a critical role in mitochondrial ATP energy production and cellular metabolism (Cordero et al., 2010).

In a case series of five patients with a diagnosis of FM and CoQ<sub>10</sub> deficiency, there was a statistically significant reduction of symptoms after receiving CoQ<sub>10</sub> 300 mg daily for 9 months (Cordero et al., 2011). All patients reported an improvement in sleep, mental alertness, and a marked decrease in joint pain. There were also significant decreases in the number of tender points, the VAS for pain, the Fibromyalgia Impact Questionnaire (FIQ), the Headache Impact Test (HIT-6), and the Migraine Disability Assessment (MIDAS).

CoQ<sub>10</sub> is generally well tolerated and has no significant adverse effects. The recommended dosing when used for treatment of FM is 300 mg daily.

### L-Carnitine

It has been suggested that FM may be associated with mitochondrial dysfunction from a deficit of carnitine. L-carnitine plays a key role in cellular energy production. Long-chain fatty acids are too large to cross the internal mitochondrial membrane and rely on L-carnitine dependant enzymatic transportation. Once in the mitochondria, fatty acids undergo beta-oxidation to adenosine triphosphate (ATP), and L-acetyl-carnitine is excreted to begin a new transport cycle (Natural Medicine Comprehensive Database, 2012).

One multicenter randomized trial compared acetyl L-carnitine (LAC) versus placebo in patients with overt FM. A statistically significant improvement was observed for depression and musculoskeletal pain in the treatment group receiving 500 mg LAC three times daily over 10 weeks. Treatment was well-tolerated (Rossini et al., 2007).

The body obtains some carnitine from red meats and dairy products and can synthesize carnitine from the amino acids, lysine, and methionine. A typical total dose of LAC is 1000 to 2000 mg daily in three divided doses. This dose would be safe in children as doses of 100 mg/kg/day are used in children with Rett syndrome (Ellaway et al., 1999).

### Sleep disorders, anxiety, restlessness

These comorbid conditions are commonly seen in patients dealing with pain and can aggravate the pain experience. There are several calming herbs and dietary supplements that may offer the desired effects to help with symptom control.

### Chamomile (*Matricaria recutita*)

As discussed previously, Chamomile is used commonly to treat nausea, nervous diarrhoea, gastrointestinal spasms, restlessness,

and insomnia. Its mechanism of action is through a known active ingredient, apigenin, which binds to benzodiazepine receptors in the central nervous system, to exert anxiolytic effects (Viola et al., 1995).

There were mixed results of efficacy in a double-blind, randomized trial of 34 adults with insomnia. A dose of 270 mg of chamomile given twice a day was used in this trial (Zick et al., 2011). Given that 1 to 3 g taken three to four times daily is the usual recommended dose to help induce relaxation or sleep (Robbers and Tyler, 1999), the dose in this trial may have been inadequate.

One heaping teaspoon of dried flower heads in half a cup of boiling water steeped for 10 min yields about 3 g of chamomile extract which can be taken up to four times a day. The dose suggested for children under 18 is one-half the adult dose. The essential oils of chamomile can also be used as aromatherapy to promote relaxation and reduce pain (Buckle, 1999). Theoretically, concomitant use with benzodiazepines or other sedatives might cause additive effects and side effects.

### Lemon balm (*Melissa officinalis*)

Lemon balm commonly is used for anxiety, insomnia, and restlessness. As an inhalant, lemon balm is used as aroma therapy for calming patients with Alzheimer's disease. Behavioural effects are attributable to a number of possible active components of the dried leaf and essential oil of the herb. Some research suggests lemon balm has acetylcholine receptor activity with both nicotinic and muscarinic binding properties (Kennedy et al., 2002).

One RCT found significant improvements in quality of sleep during 30 days of treatment with 600 mg/day of *M. officinalis* (Cerny and Schmid, 1999).

Capsules containing 100 to 200 mg of dried herb can be taken three times daily or as needed. A tea can be made steeping ½ to 1 teaspoon of dried herb in one cup of hot water for 10 min yielding 1 to 2 g taken in divided doses four times a day. It has a long history of safe usage with no worrisome side effects (Wong et al., 1998).

### Melatonin

Melatonin traditionally has been used for insomnia, delayed sleep phase syndrome (DSPS), circadian rhythm disorders in the blind, and jet lag. Melatonin is a hormone synthesized endogenously in the pineal gland produced from tryptophan → 5-hydroxytryptophan → serotonin → N-acetylserotonin → melatonin. In the brain, melatonin appears to increase the binding of GABA, the primary inhibitory neurotransmitter, to its receptors (Munoz-Hoyos et al., 1998). Melatonin production is influenced by day/night cycles. Light, both natural and artificial, inhibits melatonin secretion and darkness stimulates secretion (Brzezinski, 1997).

A meta-analysis of data of randomized controlled trials which included four studies totalling 226 children showed that melatonin treatment advanced mean endogenous melatonin onset by 1.18 h (95% confidence interval (CI): 0.89–1.48 h) and clock hour of sleep onset by 0.67 h (95% CI: 0.45–0.89 h). Melatonin decreased sleep-onset latency by 23.27 min (95% CI: 4.83–41.72 min) (van Geijlswijk et al., 2010).

A typical dose for insomnia is 0.3 to 5 mg at bedtime. Start with the lowest dose and increase to higher levels if needed. Implement

other sleep hygiene strategies (removal of environmental stimulants 1 to 2 h before bedtime, dusk simulation, quiet evening activities, etc.) to improve effectiveness.

### L-tryptophan/5-HTP

L-tryptophan is an essential amino acid absorbed from dietary protein sources that is converted to serotonin and melatonin by the earlier described pathway. People typically use this orally for insomnia, sleep apnoea, depression, anxiety, and myofascial pain.

In clinical studies, 1 g of L-tryptophan significantly reduced sleep latency, with lower doses (0.25–0.5 g) producing a trend in the same direction (Hartmann and Spinweber, 1979). Clinical evidence suggests L-tryptophan is as helpful as light therapy in the treatment of seasonal affective disorder (Ghadirian et al., 1998).

Theoretically, concomitant use with medications that cause sedation may have additive effects. Also, combining serotonergic antidepressants with L-tryptophan/5-HTP may increase the risk of serotonin syndrome.

Consider a starting dose of 50 mg 30 min before bedtime. If not effective, increase by 50 mg each night to a maximum of 300 mg per night for children and adolescents. Occasionally individuals may feel more energized taking this at night. In that case, dose with 50 to 100 mg three times a day with meals.

### Valerian (*Valeriana officinalis*)

Valerian, also known as 'nature's Valium', has been used for insomnia, anxiety-associated restlessness and sleeping disorders, mood disorders, and chronic fatigue syndrome. Valerenic acid and other constituents of valerian are GABA agonists (Natural Medicine Comprehensive Database, 2012).

An extract of valerian and lemon balm reduced restlessness and difficulties falling asleep in an open multicenter post marketing surveillance study of 918 children under age 12 with sleep disorders. Patients took one to two tablets, each containing 160 mg of valerian and 80 mg of lemon balm, twice a day. There were no significant side effects (Müller and Klement, 2006). A systematic review of the available literature suggests that valerian improves sleep quality without producing side effects (Bent et al., 2006). Some evidence shows that valerian reduces self-reported stress in social anxiety (Kohnen and Oswald, 1998).

Dosing of 100 to 300 mg 30 min before bedtime is recommended for sleep. It can also be dosed on a three-times-a-day schedule for anxiety. Valerian has been safely used in children in studies lasting 4 to 8 weeks. Use of valerian with other herbs and supplements with sedative properties might have synergistic effects, therefore caution should be used.

### L-Theanine

L-Theanine is the major amino acid found in green tea and historically been used for its relaxation and anti-anxiety effects. L-theanine works to reduce anxiety by increasing levels of GABA and serotonin (Lu et al., 2004). It also antagonizes glutamate and NMDA receptors (Kakuda et al., 2000).

One study evaluated the acute effects of alprazolam and L-theanine under a relaxed and experimentally induced anxiety condition. L-theanine 200 mg was superior to alprazolam 1 mg in producing a relaxed state under resting conditions (Lu et al., 2004).

Typical dosing would be 100 to 200 mg once or twice daily.

## Conclusion

The goal of this chapter is to introduce clinicians to the use of common herbs, vitamins, and dietary supplements that can be integrated into the care of children and adolescents experiencing pain. As clinicians we need to have an understanding of the benefits or potential side effects these supplements have so that we can best advise our patients in their use. The supplements outlined in this chapter, with their mechanisms of action and recommended doses, have been found to be effective and are generally regarded as safe to use in the paediatric population for various pain syndromes or symptoms associated with pain.

### Case example

Suzanne presented with a 6-month history of headache, myalgias, and fatigue. This previously healthy and energetic 16-year-old developed symptoms after a prolonged viral illness. She described her headache as 'all over pressure', rated the pain as '7' on the VAS, and made worse with bright lights and noise. She stated all her muscles were achy, 'felt heavy', and worse with any physical activity. She was sleeping 12 h every night but did not feel rested when she woke and often needed to take naps during the day. Because of the fatigue and pain, she had not attended school for over 3 months and stopped all physical activity. She rarely went outside the family home. Her mother was concerned that Suzanne was becoming more depressed because she wasn't doing her normal activities nor was she able to be with her friends.

On physical examination Suzanne appeared tired and had flat affect. Her skin was pale, but she had no rashes or bruises. She had multiple tender areas with palpation of her head, neck, and upper back. She also had tenderness all along her paraspinal muscles and of the large muscle groups of her extremities. The remainder of her examination was otherwise normal.

Laboratory investigations done to assess for anaemia, infection, thyroid dysfunction, and autoimmune diseases were all normal. Her RBC magnesium level was low at 3.5 mg/dL (normal 4.7–7.0 mg/dL), homocysteine level high at 12 µmol/L (normal <8 µmol/L), 25-hydroxyvitamin D level low at 17 ng/ml (ideal 50–60 ng/ml), and coenzyme Q<sub>10</sub> level was low-normal at 0.6 mcg/ml (normal 0.5–1.5 mcg/ml).

She was started on vitamin D<sub>3</sub> 4000 IU daily, magnesium malate 500 mg twice daily, and CoQ<sub>10</sub> 300 mg daily for the obvious deficiencies and for their known effects on headache pain and myalgias. She was also started on vitamin B-50 complex to provide the cofactors necessary for enzyme and energy production. She was encouraged to continue a healthy diet of lean meats, fresh fruits, and vegetables to provide other essential micronutrients. For sleep and mood, she started 5-HTP 100 mg before bedtime to boost serotonin and melatonin production, instructed on sleep hygiene strategies, encouraged to maintain a routine sleep/wake schedule every day, and asked to minimize naps to only 30 min a day. She was started on a low-intensity exercise programme of stretching followed by walking 15 min day for the first week. The time was increased only 5 min each week so as not to over-exert and trigger more fatigue/pain.

Suzanne returned for follow up 2 months later and was considerably better by her report. She was now sleeping consistently 10

h each night and felt rested when she woke in the morning. She stopped taking naps during the day, no longer had the achy muscles and was walking without fatigue about 40 min a day. She still had occasional headaches, but these were shorter in duration and intensity and could be relieved by acetaminophen. Both she and her mother reported an improved mood. Suzanne was spending more time with friends and attending school half-days with plans to return full time the following week.

Since she was clinically improved, no further laboratory tests were done. She was encouraged to continue the current regimen of supplements until she had full resolution of the symptoms and was back to her usual level of physical activity. At that time she could consider coming off the supplements and monitor for any recurrence of the symptoms.

## CHAPTER 60

# Complementary therapy in paediatric pain

Lonnie K. Zeltzer

### Summary

There is increasing paediatric use of complementary therapies (CTs), especially for paediatric pain. This chapter reviews the key literature on studies that pertain to CTs that impact pain in children. The research is still in its infancy with few studies that have been well designed and replicated. Likely the strongest of the studies is in hypnotherapy, which will have its own chapter, and in biofeedback for headaches. Acupuncture research is growing but there are few well designed studies in children compared to those in adults. Risks in CTs mostly relate to training of the practitioner and good clinical judgement (e.g. avoiding massage in children averse to touch). Most are safe when used with clinical judgement.

### Introduction

The biopsychosocial model for understanding and treating childhood pain takes into account the many facets of and contributors to the pain experience and pain-related functional disability. Increasingly, paediatric pain programmes are incorporating complementary therapy (CT) into their existing programmes of pharmacological, physical, and psychological pain management. Typically, this quadruple of treatments is called 'integrative pain management'.

A barrier to incorporating CTs into a more traditional approach to pain treatment in children is the relatively little published science to indicate which CTs are effective and safe and for what pain conditions. The implementation of many complementary practices is often not well described.

The aim of this chapter is to present a state of the science on CTs in childhood pain, and how they would be applied to children in pain. A case of the use of complementary CTs for childhood pain is presented by an adolescent patient with discussion by the author about the choice of therapies and the integration of CTs into the total treatment plan.

The various terms for CTs, typically known collectively as complementary and alternative medicine (CAM), have been used inconsistently in the literature. Not uncommonly, the terms 'complementary', 'alternative', 'holistic', and 'integrative' have been used interchangeably. Over time there also has been a blurring of boundaries between complementary and 'traditional' therapies, as

usage of CTs has become more common and the science has moved forward.

The National Center for Complementary and Alternative Medicine (NCCAM) at the National Institutes of Health has defined 'complementary therapies' as those interventional strategies used in conjunction with conventional medicine. 'Alternative therapies' are defined as treatments used in place of conventional medicine. NCCAM has divided these complementary and alternative therapies into five categories: biologically based therapies, manipulative and body-based therapies, energy therapies, mind-body interventions, and alternative medical systems. Biologically based therapies include herbal remedies that employ plant preparations for therapeutic effects, as well as vitamins and other dietary supplements. Manipulative and body-based methods include, for example, chiropractic, osteopathic manipulations, and massage. Energy therapies include Reiki and the unconventional use of electromagnetic fields. Mind-body interventions relate to techniques to increase the mind's capacity to enhance bodily function and reduce symptoms, such as hypnotherapy, biofeedback, meditation, prayer, and expressive therapies such as music, art, or dance therapy. Alternative medical systems are built upon complete systems of theory and practice and may make use of therapies from the biological, body-based, mind-body, and energy modalities. Examples are homeopathic medicine, Ayurvedic healing, naturopathic medicine, and traditional Chinese medicine (TCM). An individual complementary therapy may be used in isolation from its use within an alternative medical system, such as acupuncture (TCM) and yoga (Ayurvedic healing). Although CAM clearly encompasses a variety of techniques from various schools of thought, this chapter will focus on CTs that have been reported to have been used for acute or chronic pain in children.

### Background

Estimates of the use of CTs range from 2% in a healthy sample of children (Davis and Darden, 2003) to as high as 73% in children with cancer (Neuhouser et al., 2001), with figures pointing to substantial increases across paediatric populations. The use of CTs in children is increasing internationally, but the reported prevalence differs by country, methodology, and populations studied

(Efe et al., 2013; Heath et al., 2012; Snyder and Brown, 2012). For example, the prevalence of CT use in the Netherlands in children with cancer was found to be about 40%, while it was 11% in a Finnish study based on a national data set of over 6000 children. In the latter study, symptom reduction was the primary reason for parents seeking complementary therapies (Singendonk et al., 2013; Siponen et al., 2012). CT use often goes unreported to physicians; as many as half of all adults using CTs do so without consulting a practitioner (Eisenberg et al., 1993) and the figure may be even higher for children (Spiegelblatt et al., 1994). This practice appears to occur despite the desire of many parents to discuss their child's use of CTs with the family paediatrician (Sibinga et al., 2004).

In addition, a 2001 survey of 745 members of the American Academy of Paediatrics found that 87 % of paediatricians had been asked about CTs by a patient or a parent in the 3 months prior to the survey (Sawni-Sikand et al., 2002; Yussman et al., 2004). The paediatricians were asked most often about herbs and dietary supplements (Wilson et al., 2006; Woolf, 2003).

The 2007 National Health Interview Survey gathered information on CT use among more than 9000 children younger than 18 years (Barnes et al., 2008). Nearly 12% had used some form of CTs during the past 12 months. CT use was much more likely among children whose parents also used CTs. Adolescents aged 12 to 17 years, children with multiple health conditions, and those whose families delayed or did not use conventional medical care because of cost were also more likely to use CTs. The most common pain conditions for which CTs were used in the past 12 months included back or neck pain (8%), musculoskeletal conditions (4%), and abdominal pain (1%), with associated problems including anxiety/stress (5%), sleep problems (2%), and depression (1%). Headaches were not included in the list but related sinusitis was 2% and 'other' was (8%). Chiropractic or osteopathic manipulations were used in 3% of children, deep breathing exercises in 3%, yoga in 2%, meditation and massage in 1% each, and all other modalities were less than 1%. Integrative care including CTs is now included in major textbooks of paediatrics (Zeltzer and Krane, 2011).

## Complementary therapies

### Acupuncture and related techniques

Within TCM, there is a belief that an energy force flows through the body, which, if blocked, causes imbalance and sickness. Different traditions call this energy 'Qi' (pronounced 'chi'), prana, and 'life force'. Acupuncture is intended to restore natural energy (Qi) through the insertion of needles into points along energy pathways (meridians) in the body. The needles help stimulate the energy flow. Usually, needles are inserted into the skin from ¼ to 1 inch deep. The patient often reports light cramping, heaviness, distention, tingling, or electric sensation either around the needle or travelling up or down the energy pathway. Although the precise analgesic mechanisms have not been identified, it is likely that the body's nervous system, neurotransmitters, and endogenous substances are involved in needle stimulation (Ma 2004).

In adults, acupuncture is one of the most popular complementary therapies, yet it is less often used in children (Barnes et al., 2008). The common assumption that most children are fearful of needles may cause physicians to be averse to recommending acupuncture; yet research has found that children and adolescents find

the experience acceptable (Kemper et al., 2000; Waterhouse et al., 2000; Zeltzer et al., 2002).

In treating paediatric pain, acupuncture therapy has been evaluated for its potential effectiveness in alleviating chronic headaches (Pintov et al., 1997; Pothmann et al., 2009), acute pain (Wu et al., 2009) and surgical pain (Kim et al., 2006; Lin et al., 2009). A study investigating the efficacy of laser acupuncture in 43 paediatric patients suffering with chronic headaches, randomized children to an intervention group that used low-level laser for individualized acupuncture or to a control condition of sham laser acupuncture. The intervention group had a significant decrease in headache frequency, monthly headache hours, and headache pain intensity compared to baseline but not to the sham intervention. No adverse events were observed in the study (Pothmann et al., 2009).

Pintov et al. (1997) studied acupuncture for migraine treatment in children, with 12 patients randomly assigned to the true acupuncture group (TA) and ten assigned to the placebo acupuncture group (PA). The PA group received a sham acupuncture treatment by the insertion of the same size needle into the stratum corneum. Both the TA and PA groups received ten weekly sessions of intervention. The TA group had a significant reduction in both frequency and intensity of migraines and a significantly potentiated amount of panopioid activity after the acupuncture compared to that found in the PA group.

These studies (Pintov et al., 1997; Pothmann et al., 2009) provide some evidence for acupuncture effectiveness in treating chronic headaches in children, although limited by small sample sizes and the challenges of providing a sham treatment (such as the inability to double blind). The Pintov study had a biased sample by excluding children who were receiving any headache medication. Yet, these early results are promising and more randomized controlled trials (RCTs) are warranted.

A non-randomized clinical trial (Wu et al., 2009) assessed two 10 to 15 min acupuncture sessions in 11 hospitalized children with spinal fusion surgery and nine in intensive care (PICU). Both groups had a general decrease in pain scores, heart rate and systolic blood pressure after acupuncture sessions. The non-PICU group 1 had a maximal decrease of morphine PCA usage 4 to 8 h after the first acupuncture session and by the second session were placed on oral opioids. This study showed acceptance and tolerance for acupuncture for postoperative pain management within a hospital setting, although efficacy was not determined.

Lin et al. (2009) randomized 66 children aged 2.2±1.4 years undergoing bilateral myringotomy/tympanostomy tube (BMT) placement into a post-anaesthesia preoperative acupuncture or control condition without the acupuncture. The intervention group had significantly lower pain and agitation scores across the different observed time points and a lower need for postoperative acetaminophen. No adverse events were observed. Long-term effects have yet to be determined.

A study (Kim et al., 2006) of capsaicin plaster placed at the Zusanli (Z:ST-36) points after a unilateral hernia repair for postoperative pain control in 108 children (4 months to 9 years) randomly assigned patient to three groups. The intervention group (Z) received capsaicin plaster at Z acupoints and placebo tape at a non-acupoint in the shoulder. The sham group (S) received plaster at shoulder points and placebo tape at the Z acupoint. The control group (C) received placebo tape at both shoulder and Z points. Outcome measures were postoperative pain scores, as

well as the analgesic opioid requirements during the 24 h postoperative time frame. A significantly lower use of meperidine (the postoperative opioid used in the study) was found in group The Z group had less opioid use and lower pain scores compared to the other two groups. No side effects from capsicum plaster were observed.

These studies (Kim et al., 2006; Lin et al., 2009) suggest a potentially safe complementary therapy for reduction of opioid analgesic dosage for paediatric post-operative pain management. Replication of the studies and improved study designs are warranted.

Acupuncture practitioners are licensed and regulated health care professionals in about half the states in the US. In states that do not currently require licensing, the acupuncture practitioner should be asked if he/she is certified by the National Commission for the Certification of Acupuncturists. The acupuncturist should be asked to communicate with the child's paediatrician or pain specialist for optimal integrative care. Acupuncture in Canada developed in the late 1800's primarily in Chinese communities but gradually spread to the communities until it was incorporated into the Governmental health care system. For example, in the province of Ontario, it became part of the 'Traditional Chinese Medicine Act' in 2006 (Wang and Wu 2012). Across Asia, acupuncture has been accepted and used for hundreds of years. The governmental regulations for practising acupuncture differ by country worldwide but in most places few restrictions are in place.

## Biofeedback

Biofeedback uses a computer or other bodily feedback tool to help children to reduce pain or other symptoms by noticing and then learning strategies to control physiological changes associated with the stress response. These monitored changes (Evans and Zeltzer 2008) may include muscle tension, peripheral skin temperature, sweat gland response, brain wave activity, or breathing rate, with the goal of increasing the body's relaxation response. Using biofeedback helps children learn about their body's responses to stress and become aware of their own abilities to alter those responses. Biofeedback is especially popular for the treatment of migraine and headaches in children (Evans and Zeltzer, 2008).

Biofeedback has been evaluated in its effectiveness for treating paediatric headaches (Arndorfer and Allen, 2001; Bussone et al., 1998; Fentress et al., 1986; Grazi et al., 1990, 2001; Kroner-Herwig et al. 1998; Scharff et al., 2002) and abdominal pain (Schurman et al., 2010; Sowder et al., 2010). Fentress et al. (1986) randomized 18 children, ages 8 to 12 years, who had recurrent intermittent headaches and were not on preventive medication, to a biofeedback with or without a relaxation response (RR) condition or to a control wait-list group for seven weekly then two bi-weekly sessions. Headache diaries were evaluated throughout the study and at a 1-year follow-up assessment. Outcome measures included frequency of headaches, total of hours of headache, and severity of headaches. Compared to control group, both treatment groups had improvement in their headache diary measures compared to baseline and at the end of the 15-week study period. However, no differences were found between baseline and the 1 year assessment. No differences in the RR groups were found with or without biofeedback. The study was limited by small sample size, no reporting of missing data, and other design problems.

Bussone et al. (1998) randomized 30 children, ages 11 to 15 years, with episodic tension-type headache to either a biofeedback-relaxation

(BFB-REL) intervention or a relaxation placebo (REL-PLAC) control condition for ten sessions, two per week. Both groups had a 55% improvement in headache severity at the one month assessment, but only the BFB-REL group had improvement at the 6- and 12-month follow-ups, with an 85% improvement by the last assessment.

Kroner-Herwig et al. (1998) randomized 40 children, ages 8 to 14 years, with tension-type or combined headaches to an electromyographic (EMG)-frontalis biofeedback or progressive relaxation (PR) condition with and without parental involvement (PI) or to a wait list control group. There were 12 bi-weekly sessions and the parent condition included three 1 h parent sessions. All four intervention groups had significant main effects in all outcome domains post-intervention. Yet, at the 6-month assessment, the biofeedback group without PI showing the greatest changes, followed by biofeedback with PI, PR alone, PR with PI, and then the control group. The biofeedback group without PI had the highest mean effect size for headache outcomes. Adding parents did not appear to improve the intervention effects.

Grazi et al. (1990) provided EMG biofeedback to ten children, ages 12 to 15 years, with tension headache twice weekly for 6 weeks. Pain Total Index collected with a headache diary and muscular tension scores decreased in all patients from baseline to treatment completion. Grazi et al. (2001) provided an EMG biofeedback-assisted relaxation programme in 54 children, mean 12 years, with episodic tension-type headaches with two treatment sessions per week for 5 weeks. Pain Total Index via daily diaries were significant at treatment termination but not at the 1-year follow-up. At the 3-year assessment, 84% of the participants were symptom-free. Given the lack of a control condition, the percentage of children who would have been headache free even without intervention at 3 years is unknown. Other study design weaknesses limit strength of the findings.

Arndorfer and Allen (2001) conducted a within-subject, multiple baseline, time-lagged study to evaluate thermal biofeedback therapy in five children, aged 8 to 14 years, with tension-type headaches. Baseline data over 4 to 7 weeks were followed by six thermal biofeedback treatments. All participants showed clinical improvement via daily headache diaries and four of the five were headache-free at 6 months. Lack of a control condition and small sample size limited the importance of the findings.

Scharff et al.'s (2002) study randomized children (7–17 years) with migraines to a stress management with thermal biofeedback (TB), hand-cooling biofeedback (HCB) without stress management, and an assessment control condition to reduce pain, anxiety, and depression. At the 6-week post-treatment assessment, no one in the control condition had headache improvement, while one child (10%) in the HCB and seven (54%) in TB group had significant reduction in headache severity. In a combined analysis, both treatment groups had reduced headache severity and frequency. No changes were in anxiety or depression measures. The same findings held for the 6-month follow-up. While this study is often cited as evidence of thermal biofeedback for migraines in children and despite its promising title, caution is warranted because of the many confounds that limit generalizability of the findings.

Sowder et al. (2010) provided six sessions of heart rate variability (HRV) biofeedback to restore vagal tone in 20 children, 5 to 17 years, with functional abdominal pain (FAP) and compared outcomes to ten children without FAP. The significant decrease in low frequency/high frequency (LF/HF) ratio after

intervention suggested an improvement in cardiac vagal tone, along with a decrease in pain frequency and a significant correlation between the decrease in LF/HF ratios and pain frequency. This novel study of heart rate variability biofeedback in FAP was limited by the study design (no randomized trial with a control condition).

Schurman et al. (2010) randomized 20 children, ages 8 to 17 years, with functional abdominal pain (FAP) to a ten-session biofeedback-assisted relaxation training (BART) or control condition. Children in the intervention group demonstrated significantly improved pain intensity, duration of pain episodes, and overall clinical improvement in comparison to the control group. A good review of biofeedback for children's headache is found in Hermann and Blanchard (2002).

Does the discussed literature suggest strong support for the clinical utility of biofeedback for pain reduction in children? The data are suggestive but not strong. That being said, there are many individual children who report great benefit and report that biofeedback enables them to cope, attend school, and sleep well at night. Since the primary downside is cost in those countries where families have to pay out of pocket for this treatment, providing targeted biofeedback to children who need self-management tools to cope with pain and become more functional and less distressed by the pain is recommended. Targeted biofeedback means tools for learning muscle tension reduction in those body areas where muscle tension is a primary cause or contributor to the pain. Skin temperature warming might be appropriate for children with migraines, while adding EMG biofeedback would be useful if there were myofascial contributors to the headaches. Biofeedback seems to be especially useful for the child who seems to enjoy and learn best from computers and other 'gadgets'. The biofeedback clinician should be well trained in his/her craft and not promise 'amazing' results so that children who do not find it useful will not feel like they failed.

## Yoga

There are many types of yoga, often named after the lineage of the school of yoga or founder of a certain tradition (the guru). In Iyengar yoga, developed by B. K. S. Iyengar (Evans et al., 2010, 2011c; Woolery et al., 2004), therapeutics provides a series of poses matched to the symptom and medical needs of the child and the pose series changes as the child improves. The poses ('asanas') are intended to correct health-related problems, both in body structure and in internal organ function. The goal is to enhance mindfulness of the body, feelings of centeredness and calm, and a sense of self-control. The poses are intended to address underlying causes of symptoms and poor postural habits that may contribute to the child's pain. The goal of treatment is to help children to learn how to change these bodily contributors to pain.

Yoga has been studied in with irritable bowel syndrome (IBS; Brands et al., 2011; Kuttner et al., 2006) and in cancer (Geyer et al., 2011). Kuttner et al. (2006) randomly assigned 25 adolescents, 11 to 18 years, with IBS to a yoga or wait-list control group. The yoga group had a single yoga session in person followed by 4 weeks of expected home practice with video guidance. The yoga group reported lower levels of emotion-focused avoidance, functional disability, and anxiety compared to the control group. Evaluating

pre- and postintervention effects, merging yoga groups including those who had yoga after being in the control condition found a significant reduction in gastrointestinal symptoms. This study was limited by no monitoring for home practice adherence and small sample size.

Brands et al. (2011) evaluated the effects of ten sessions of yoga in 20 children, 8 to 18 years, with functional abdominal pain (FAP), dividing participants into groups of 8 to 11 or 12 to 18 years. Pain frequency was significantly reduced for children in both age groups at the end of the treatment, but only the younger group maintained reduced pain frequency at 3-month follow-up. This single arm study had multiple design problems.

Geyer et al. (2011) carried out five-weekly yoga sessions to determine feasibility in six hospitalized children with cancer, ages 6 to 19 years. Study feasibility with this population was supported.

Most yoga studies lack a manualized intervention where poses for the study are shown so the study could be replicated, even with individualized adjustments based on children's needs during the sessions (Evans et al., 2009). More studies of yoga for children's pain are needed and should include mechanisms and outcomes (Evans et al., 2011b).

That being said, safe types of yoga, such as hatha yoga and Iyengar yoga in which practitioners have extensive training and certification processes, can be extremely beneficial for stretching, relaxation, and body balance. Also the yoga poses give children a tool that they can use independent of requiring a clinician to 'do something' to them. In our programme we have been studying Iyengar yoga for young people with arthritis, irritable bowel syndrome, and fatigue in young survivors of childhood cancer. Across studies, participants overall feel better and want to continue with the yoga (Evans et al., 2009, 2010, 2011a, 2011b, 2011c; Woolery et al., 2004).

## Chiropractic

There is limited research in chiropractic care to treat paediatric pain. Hayden et al. (2003) randomly selected 15 chiropractors from four cities in Canada to provide data on their paediatric patients with low back pain. The response was positive and there were no reported complications. Roberts and Wolfe (2009) describe complete resolution of pain after chiropractic treatment with a 6-year-old girl with multiple sites of pain following an injury with persistent long-term outcomes. Hewitt (1994) describes complete resolution of head and neck pain in a 13-year-old girl whose symptoms had persisted for the previous year after four chiropractic treatments. The data on chiropractic care for children's pain are lacking. A recent literature review of studies of spinal manipulation in children found limited studies of paediatric chiropractic overall, and nothing on spinal manipulation for back pain (Gleberzon et al., 2012). The most positive findings in this review were for asthma.

Another review found through analyses of a national data set in the US that neck and back pain were the most common reasons for chiropractic or osteopathic spinal manipulation, and that teens were more likely to use these therapies than were children (Ndetan et al., 2012). As Gilmour et al. (2011) note, practitioners should have training in the care of chiropractic with children before practising this therapy on them.

## Aromatherapy

There are very few studies evaluating the effects of aromatherapy as a complementary tool in alleviating pain in paediatric patients. The few studies conducted (de Jong et al., 2012; Ndao et al., 2012) have concluded little or no significant benefits. In an observer blinded, randomized, controlled trial, de Jong et al. (2012) randomized to one of two intervention conditions (massage with or without mandarin oil) or to a usual treatment control group 60 infants, ages 3 to 36 months, for improvement in postoperative pain after major craniofacial surgery. No significant differences were found in pain or distress after intervention in any of the three groups. Only heart rate and mean arterial blood pressure were reduced in the two intervention conditions. Limitations were lack of assessment of treatment adherence, no delayed outcome evaluations, and other design flaws.

Ndao et al. (2012) randomly assigned to an aromatherapy (bergamot essential oil) or placebo group 37 children, ages 5 to 21 years, undergoing stem cell transplantation (SCT). The control group had an aromatherapy diffuser with a non-essential oil-based scented shampoo during SCT. The intervention group had significantly higher anxiety and more nausea than did the control group. The findings suggest that bergamot essential oil may increase rather than reduce symptoms in children undergoing SCT.

In summary, the studies are weak or do not support specific benefits of aromatherapy on symptoms in children's pain. More studies are needed and clinically, unless requested by the child or adolescent, it should not be automatically used.

## Pet therapy

Dogs have been trained to help distressed children in a process called pet therapy, animal-assisted therapy (AAT), or canine visitation therapy (CVT). Braun et al. (2009) evaluated AAT to reduce pain in 18 children, ages 3 to 17 years, in an acute care setting with an established AAT programme. Outcomes were compared to those in 39 children without AAT. Group assignment was not described. AAT was described as having the dog match the child's breathing pattern by sitting next to the child. How this was done or measured is not described. The AAT group had significantly less pain but higher respiratory rates than did the comparison group without AAT. Blood pressure, heart, and respiratory rates did not differ between groups.

Sobo et al. (2006) found reduced pain after a single CVT for 25 children, ages 5 to 18 years, with acute postoperative pain in a hospital already with an existing CVT. The children reported that the dog provided distraction from pain, entertainment, pleasure/happiness, contact/snuggling, was calming, and eased the pain. Study limitations are clear in this descriptive study.

Overall, the studies of AAT have covered horse-assisted therapy (hippotherapy), which has been used most commonly for children with cerebral palsy, and dogs as pet therapy. Many children's hospitals now have trained pets spend time with children. Dogs are also trained in special programmes to be of eye, hearing, limb extender, and other services to children with specific disabilities. A recent study, while not in children, concludes after reviewing the literature that, while encouraging, study findings for specific significant symptom effects are weak (Muñoz et al., 2011).

## Massage and touch therapies

Massage and various forms of touch have been reported clinically to be helpful and soothing, at least in adults. The effectiveness of massage has been studied in children with chronic pain (Suresh et al., 2008), rheumatoid arthritis (Field et al., 1997), sickle-cell disease (Lemanek et al., 2009), burns (Gurol et al., 2010; Hernandez-Reif et al., 2001), cancer (Post-White et al., 2009), haematopoietic cell transplant (Ackerman et al., 2012; Wolf et al., 2012), and cerebral palsy (Nilsson et al., 2011).

Suresh et al. (2008) compared symptom outcomes after 80 massage sessions with 57 children, mean 13.9 years, in an outpatient chronic pain clinic. Pain and other symptoms were reported to have improved after the massage while no symptom improvements were found in a comparison group of 25 children who did not receive massage. The study has many design flaws.

Field et al. (1997) randomized 20 children, ages 5 to 15 years, with juvenile idiopathic arthritis to a massage or relaxation group. Parents were trained to provide their child with a 15 min bedtime massage for a month, while the parents in the comparison condition guided their child in 15 min of relaxation. Outcome assessments were made pre/post intervention on the first and last treatment sessions. Parent and child reported decreased anxiety and pain and lower salivary cortisol levels were found in the massage versus the relaxation groups. Methodological problems included no assessment of treatment adherence or integrity.

Lemanek et al. (2009) randomly assigned 34 children with sickle cell disease to a massage or attention control condition. Parents were trained and asked to provide a 20 min daily massage to their child for 30 days, while the massage therapist made weekly home visits to provide massages. Parents and children in the control condition completed weekly assessments. Parents in the intervention group had significantly higher anxiety and depression than did those in the control group. Children in the intervention group reported higher functional status and lower depression, anxiety, and pain than did those in the control children. No significant group differences were found in health care utilization. Limitations were lack of measures of treatment integrity and adherence, and a control group that was not truly an attention control condition.

Hernandez-Reif et al. (2001) randomly assigned 24 children, mean age 29.3 months, who were getting dressing changes for severe burns to a massage or standard care control condition. The massage group received a 15 min massage from a trained therapist before a dressing change, while the therapist talked with the control group for 15 min before the dressing change. Children in the massage group had significantly less behavioural distress, less nurse-reported difficulty with dressing changes, and less therapist-reported child distress and less self-reported stress compared to the children in the control condition. While a good attention control condition was provided within the study design, child behaviour was the only blinded assessment, and there was no assessment of treatment integrity.

Gurol et al. (2010) compared 5 weeks of twice weekly massage to usual care in 63 burned adolescents, 12 to 18 years of age, using convenience sampling method for group assignment. Adolescents receiving massage reported lower itching, pain and anxiety pre/post intervention while only itching was reduced in the control group. Lack of randomization and no measures of treatment integrity weakened the findings.

Post-White et al. (2009) conducted a randomized crossover pilot study evaluating massage therapy (MT) or quiet-time (QT) in 23 children, ages 1 to 18 years, with cancer receiving chemotherapy. The MT group had four weekly sessions of parents receiving massage followed by child massage by massage therapists. The QT group had matched quiet rest or quiet toy time. Heart rate was significantly lower in the MT children but no significant differences were found in respiratory rate, systolic or diastolic blood pressure, nausea, fatigue, anxiety or salivary cortisol. Parental anxiety was significantly less in the MT group, but parental fatigue was significantly reduced only in the QT group. The study design was excellent but other weaknesses, including the wide age range of children weakened the generalizability of the findings.

Wolf et al. (2012) compared thrice weekly Swedish/acupressure massage to usual care in 23 children, ages 5 to 18 years, receiving haematopoietic cell transplant (HCT). Lack of significant findings were likely related to insufficient power, but children receiving the massage-acupressure had fewer days of mucositis (ES 0.63), lower overall burden of symptoms (ES 0.26), improved fatigue (ES 0.86) and fewer symptoms of pain (ES 0.42), and nausea (ES 0.62). There was no difference in hospital stay between the groups.

Ackerman et al. (2012) randomized 23 children, 5 to 18 years of age, who were undergoing stem cell transplantation to a three week parent-provided massage or control condition. Parent interviews were positive about the massage effects on their child but coordination with clinical hospital routine was difficult. During acute pain episodes, children did not want the massage. Nilsson et al. (2011) studied effects of massage in orthopaedic postoperative pain management of six children with cerebral palsy. The massage therapists noted that it was important to assess the child's response to touch since some children have touch aversion. Other touch therapies, such as therapeutic touch and Reiki, are illustrated by the pilot study by Kemper et al. (2009).

The state of the science suggests that massage and other touch therapies may be beneficial for pain control in children and useful clinically. Certainly children with any form of myofascial pain, unless they are hyperalgesic to light skin touch, would likely benefit from massage therapy. Children with headaches and even those with abdominal pain may also benefit. Massage should not be offered to children with a history of sexual abuse or who are otherwise averse to touch, such as some children with autism spectrum disorders. The problem to be studied is that we don't know how to match the child with the type of massage to get the most therapeutic effects with the least negative effects. Variables to be tested include child characteristic, relevant past history, and type and location of pain. Therapist variables include training, experience with children, and sensitivity to children's body language. Massage variables include amount of pressure, muscle versus skin massage, over clothes or with direct bodily contact, use of lotions or aromatic oils, and duration, frequency, and total length of therapy. Context variables include location of massage, timing, and others' presence.

## Art therapy

Art therapy is the use of various art media forms for both distraction and for self-expression, sometimes with therapist/child interpretation, to help children to cope with distress and pain. There are early reports of the value of art therapy in the paediatric hospital setting (Sundaram 1995).

Favara-Scacco et al. (2001) compared art therapy in 32 leukaemic children leukaemia undergoing painful procedures with 17 previously hospitalized children, and found more positive behaviours in the art therapy group. Madden et al. (2010) randomized 16 children with brain tumours, ages 2 to 18 years, to six weekly creative art therapy (CAT) sessions or a reading control condition. The CAT group was found to have greater parent-reported improvement in child pain and nausea. A single CAT session in a cohort of 32 children was found to reduce pain and anxiety. Further study of art therapy for reduction or prevention of pain in children is still needed.

While art therapy may be therapeutic for some children with chronic pain, more quality research is needed before this modality as a complementary therapy for pain can be recommended broadly. Art therapy may be used within psychotherapeutic treatment for coping, anxiety, or depression in children with pain, but art therapy specifically for pain control is not yet supported by research findings.

## Music therapy

Music can be considered as a distractor from pain and studies have looked at the use of music during acute pain settings. In music as a distractor, little is known about the effects of type of music, child choice, duration of the music, or music volume, pitch, rhythm, or impact of instruments with or without vocals. Music as a distractor or relaxation tool is different than music therapy. Unfortunately, there are few studies of music therapy for paediatric pain. A descriptive study suggests benefits in paediatric palliative care (Lindenfelser et al., 2012). Robb et al. (2011) report on fidelity strategies in a Children's Oncology Group clinical trial of a therapeutic music video intervention for oncology patients, ages 11 to 24 years undergoing stem cell transplant.

While not a study in children, Tan et al. (2010) randomized 29 burn unit inpatients to music therapy or a control condition in randomized, crossover design for dressing changes in which patients were randomized to receive music therapy on the first or second of two consecutive days. During intervention days, patients carried out music-assisted relaxation with self-guided imagery before and after dressing changes, while creating music during dressing changes. Pain before ( $P < 0.025$ ), during ( $P < 0.05$ ), and after ( $P < 0.025$ ) dressing changes were found to be reduced on music therapy in contrast to control days, with a decrease in anxiety and muscle tension during ( $P < 0.05$ ) and muscle tension after dressing changes ( $P < 0.025$ ). The study needs replication in children. Austin (2010) reviewed evidence and encouraged research on music therapy with children on mechanical ventilation in a paediatric intensive care unit.

Kristjánsdóttir and Kristjánsdóttir (2011) randomly assigned 118 adolescents, aged 14 years, to one of three groups receiving polio immunization: musical distraction with ( $n = 38$ ) or without headphones ( $n = 41$ ) and standard care ( $n = 39$ ). Music therapy without headphones emerged as a significant predictor of no pain. Nilsson et al. (2009) randomized 80 children, ages 7 to 18 years, undergoing day surgery to a 45 min music distraction at entry into the postoperative care unit or to usual care. The music group had fewer children receiving morphine, lower total morphine dose, and a greater decrease in facial action coding scores than did the control group but no differences in vital signs, behavioural measures, or anxiety.

Nguyen et al. (2010) randomized 40 children with cancer, ages 7 to 12 years, to music distraction or usual care for lumbar puncture (LP) pain. Both groups had earphones beginning 10 min before the LP, but self-selected music was provided only to the music group. Pain during and after procedures, anticipatory anxiety, heart and respiratory rates during and respiratory rate after the LP were significantly decreased in the music group. Young et al. (2010) provided music distraction to 50 children during an emergency room visit, with 86% reporting that listening to music was 'helpful' or 'very helpful'.

Others have also reported on music as a distraction in various paediatric settings to reduce pain (Aitken et al., 2002; Arts et al., 1994; Malone 1996; Megel et al., 1999). One recent review of music therapy in paediatrics did not include pain as an outcome (Naylor et al., 2011).

## Case example introduction

In the following paragraphs, GH, a 17-year-old girl, describes her pain experiences and her use of complementary therapies. She was first evaluated in the pain clinic when she was age 14 years with extreme leg and back pain and reduced ability to walk or sleep when the pain was severe. She had been absent from school for about 5 months because of pain. At one point she developed conversion pseudoseizures during extreme stress, although these eventually resolved. She was diagnosed with myofascial back and leg pain, an anxiety disorder, and some family-related stressors. Because she reported that she used art to express her feelings and calm herself, she was referred to our pain programme art therapist for psychotherapy through creative expression with self-interpretation and discussion. She also learned to use self-hypnosis to alter her sensory experiences, develop a sense of control over her pain, and regain control over what she described as involuntary bodily movements. She also learned an Iyengar yoga practice to strengthen and stretch key weak and contracted muscles, enhance joint flexibility within proper alignment, and to work towards maintaining emotional and musculoskeletal homeostasis within a mindful awareness paradigm. Family therapy, while needed, was not undertaken. Here is her story:

### Case example

I was lost. I was depressed. I was confused. I had never been in such a dark place as I was my freshman year of high school, experiencing pain that was strong enough to make me drop out of school and sports. While I was in bed crying, alone and scared, doctors were telling me there was no reason for my pain. The ones who had more pride than passion would guess how to fix me with treatments ranging from pills to a full body cast. I went to thirty of the top doctors in my state and they all eventually threw up their hands. I told them my back and leg hurt so they took X-rays, MRIs, and bone scans of my back and leg—nothing showed up. They ran nerve tests on me and got into fights with my dad when he wouldn't let them try an epidural on me or give me morphine. It was the most frustrating experience because with every doctor who gave up and every method that failed, my pain increased and fewer people believed me. It was an endless

inner struggle between what people were telling me and what I was really feeling. I doubted my own sanity and felt myself slowly slipping away from the hours in waiting rooms, heavy medications, and maddening pain. I started passing out and having seizures. I did not feel like a 14-year-old girl anymore. I was depressed beyond belief and I was utterly and completely alone. No one knew that the cause of the pain wasn't an injury—it was an overactive nervous system. It was stress.

When I reached the Paediatric Pain Clinic I had already lost everything. I honestly thought I was going crazy and those negative feelings only increased as I was abandoned by my closest friends. I was as low as I could get when I met the pain doctor I thought I knew everything about doctors and 'the system', but she completely surprised me. She took me off the drugs and threw away my body cast. She told me to start doing hypnotherapy, art therapy, and Iyengar yoga. At first I felt like she wasn't taking me seriously. I thought there was no possible way that drawing or painting pictures could stop my pain. I had never heard about anything like this before. My family and I were as sceptical as could be, but we really had nothing to lose at that point.

In the beginning of the process I just viewed my appointments as fun ways to relax, but those three alternative treatments ended up saving my life. They felt so easy and I enjoyed them so much that it didn't feel like therapy and they didn't make me feel like a sick kid. The hypnotherapy taught me how to force myself to relax and to respect my personality. The art therapy gave me an easy and healthy way to express myself that I'd never even considered. The Iyengar yoga helped me balance my body but also, surprisingly, to balance my mind. The stress was being resolved and the pain was finally going away.

I don't feel like either one of the therapies helped me drastically more than the others. I think it took the combination to heal and regain my health. I used to be embarrassed about my weird therapies, but now I wish I could get everyone to try them. The interesting part about these alternative therapies is that they are so personalized it really depends on what works for you. Just because hypnotherapy, art therapy, and Iyengar yoga worked for me doesn't mean they will work for everyone. Other kids might need music therapy and biofeedback to feel better. That is the best part about this method—it's whatever works for you. It doesn't just address your body—it includes your mind—your brain.

These unique therapies gave me the tools I needed to take back control of my life. When I am about to have a panic attack at a party I say I am going to use the bathroom, close the door, and do my hypnotherapy. When I come out, I feel as good as new. When I am feeling really stressed and overwhelmed but don't necessarily know specifically what is wrong, I draw about it. That usually helps me realize the problem so I can address it. When I'm shopping and I start to feel pain, I go in a dressing room, lock the door, and do Iyengar yoga on the floor. Then I can keep walking around and not have to worry about going home early.

Even though I still have pain I feel confident that it will no longer inhibit my life or restrict what I do. I have taken back control of my body and I am happy with my health. These alternative methods work and I am the proof. They didn't mask the symptoms like medication, but they didn't solve them right away either. They just gave me the tools I needed to be successful. I will forever be grateful to these therapies because I have my life back.

## Conclusion

Research in complementary therapies for paediatric pain is still in its infancy. While families turn to complementary therapies, there are reports of some cautions to be applied (Adams et al., 2011; Anonymous, 2011). Study designs are often not optimal because of lack of randomized controlled trials, appropriate controls, blinded assessors, use of standardized measures, intervention and assessment fidelity checks, and insufficient sample size for appropriate power to test the study outcomes. Age ranges are often so wide that they cross developmental stages and standardized norms for a specific measure. With small sample sizes, puberty, age and sex effects of the intervention cannot be assessed. As an example of a report intended to improve such studies, an assessment of the quality of measures in studies of complementary therapies was reviewed by Toupin et al. (2012).

Investigators who are knowledgeable about the populations that they are studying are necessary to move the field forward. This process could start with clinical experience in  $n = 1$  studies or ABA designs (where there is baseline assessment, intervention, and then assessment again after removal of the intervention), case series to determine feasibility, measurement and intervention issues, and effect size in pre/post format. Such data will help in the development and implementation of appropriate randomized clinical trials with careful attention to the control condition. One example of a control condition would be to control for social support and other group effects if the therapeutic effects of a complementary modality are being tested in a group format, such as a yoga programme. In this case the control condition might be a group education programme or group light exercise. Another study factor warranting attention is the need for appropriate placebos for the intervention, such as placebo needling without skin puncture for acupuncture studies. Appropriate statistical methods, with intention to treat analyses, descriptions of methods used for addressing missing data, treatment fidelity and data integrity checks, recruitment methods, and attrition are needed. Collaborations between the complementary therapy practitioners and the clinician/research scientists are optimal. Manualized intervention protocols, while allowing for needed individualization, will allow replication of the study and generalizability of the findings. Mixed methodologies that include both quantitative and qualitative data will provide, through patient narratives, a fuller understanding of potential reasons for effectiveness or barriers to implementation and will guide future studies.

Most clinical programmes that serve children who have chronic pain use the biopsychosocial method for evaluation and treatment. Within this model, complementary therapies play an important role within the entire treatment plan. While studies are stronger for some modalities compared to others, as noted, the lack of research does not mean that these modalities are not effective. For example, our programme includes clinicians in Iyengar yoga, hypnotherapy, acupuncture, biofeedback, craniosacral therapy, art and music therapy, physiotherapy, psychotherapy, and psychopharmacology. The team mostly resides in community practice and we meet weekly as a team for an integrative approach to treatment. Determining the specific therapy to incorporate into the child's treatment plan depends upon the type of child and the needs of the child therapeutically (e.g. complex regional pain syndrome = physiotherapy and a mind therapy such as psychotherapy, biofeedback, hypnotherapy, or mindfulness, with family psycho-education). Working

with complementary clinicians in an integrative, team format is the best way to insure safety and maximize efficacy of the treatment plan, even if the communication with these clinicians is via telephone or email. Depending upon the country, cost to the family might dictate or limit the options of therapies available to the child. Complementary therapy integrated into the traditional biopsychosocial model of evaluation and treatment for the child with chronic pain provides, in this author's opinion, optimal care for the child with pain.

## CHAPTER 61

---

# Theory-informed approaches to translating pain evidence into practice

Janet Yamada and Alison M. Hutchinson

### Summary

Despite great strides in evidence-based pain assessment and management strategies, infants and children still experience acute pain (including multiple painful procedures) and chronic pain during hospitalization. Translating best evidence on pain assessment and management into clinical practice remains a challenge. The knowledge- or evidence-to-practice gap in pain in children can be addressed by implementing strategies, underpinned by knowledge translation theories, frameworks, and models, to promote and sustain practice change. A range of factors related to the organizational context and individual behaviour play a role in the adoption of new pain assessment and management practices.

### Introduction

Access to evidence-based pain guidelines, policies, standards, and consensus statements has increased over the past decade, highlighting the importance of providing appropriate procedural pain management for infants and children anonymous (2000). In particular, evidence-based recommendations have been developed for the management of procedural pain in infants and children (Lago et al., 2009; Royal Australasian College of Physicians PCHD 2005a, 2005b), post-surgical pain and sedation (Anand et al., 2006; Yamada et al., 2008). Despite strong evidence to support the effectiveness of pain assessment and management strategies, use of such strategies for infants and children remains a challenge, highlighting a knowledge-to-practice gap (Scott-Findlay and Estabrooks, 2006). In a recent audit of paediatric pain practices from 32 hospital units in eight paediatric centres across Canada, only 28% of children who had undergone a painful procedure also received a pain management intervention specifically linked to the procedure documented in their medical chart (Stevens et al., 2011). Hospitalized infants experience an average of 12 tissue damaging procedures per day (Carbajal et al., 2008). Carbajal and colleagues (2008) reported that, of 42 413 painful procedures performed on 430 infants, pharmacological interventions were provided to only 2.1% of the infants;

18.2% painful procedures were managed using non-pharmacological strategies, and 79.2% patients received no pre-procedural analgesia. Similarly, Johnston and colleagues (2011) found that 46% of infants in neonatal intensive care units (NICUs) who were exposed to tissue damaging procedures were administered opioids for 14.5% of procedures, while in 14.3% sweet tasting solutions such as sucrose or glucose were used. These findings highlight the extent of the gap between evidence for acute pain in infants and children and its translation into practice.

This research-to-practice gap is not unique to pain management or the paediatric setting. Scholars have been exploring barriers to and facilitators of research use and studying approaches to promote uptake of evidence across a range of healthcare settings. Additionally, behavioural, psychological, and social theories, frameworks, and models have been used to guide and explain health professionals' practice changes. In this chapter, knowledge translation (KT) in the context of paediatric pain assessment and management is described and discussed.

### Definition of knowledge translation

Numerous terms are used to describe KT; the purpose is to promote the use of evidence to optimize outcomes for recipients of healthcare. The term *knowledge translation* is used to describe the *process* of translating evidence into practice and/or to refer to the use of research as an event or *outcome*. One comprehensive and frequently cited definition of KT is that of the Canadian Institutes of Health Research (CIHR), which is:

A dynamic and iterative process that includes synthesis, dissemination, exchange and ethically-sound application of knowledge to improve the health of Canadians, provide more effective health services and products and strengthen the healthcare system. (Canadian Institutes of Health Research: <<http://www.cihr-irsc.gc.ca/e/29418.html>>)

According to Graham et al. (2006), implicit in this definition is that *knowledge* refers predominantly to research evidence. Terms used synonymously with KT include knowledge transfer, knowledge

uptake, knowledge utilization, knowledge exchange, knowledge implementation, knowledge dissemination, innovation diffusion, implementation science, and research utilization. Arguably, some of these terms have a different and/or narrower meaning than that of KT.

## Why use a theory-informed approach to KT?

In the field of KT, increasing emphasis has been placed on the importance of using theory to inform: (1) selection and development of strategies to promote implementation of KT interventions, and (2) evaluation of the implementation strategies (Eccles et al., 2005; Rycroft-Malone and Bucknall 2010; Sales et al., 2006). Systematic review evidence exists for the effectiveness of a number of KT interventions (Bero et al., 1998; Grimshaw et al., 2001; Oxman et al., 1995; Prior et al., 2008; Wensing et al., 2006). However, the evidence indicates that effectiveness of such interventions varies; they are effective in some situations but not all (Hrisos et al., 2008a, 2008b). A theory-informed approach can help provide an understanding of what has been described as the ‘black box’; that is, theory can illuminate how, why and under what circumstances an intervention works (Hrisos et al., 2008a, 2008b; Rycroft-Malone, 2007). According to the UK Medical Research Council Framework for Developing and Evaluating Complex Interventions (2008), interventions should be underpinned by a coherent theory and the theory should be used, systematically, to develop the intervention. A theoretical understanding about how an intervention influences behaviour enables weaknesses in, and barriers to the success of the intervention, to be targeted and overcome.

## What do we mean by theory, frameworks, and models?

### Theory

Theories can be used to describe, explain, and predict, for example, health professionals’ behaviours related to KT (Rycroft-Malone and Bucknall, 2010). Behavioural theories have been described on a knowledge continuum ranging from broad to narrow in scope. Mid-range theories, such as the theory of planned behaviour (Ajzen, 1991), are less abstract and more concrete compared to macro or grand theories. Mid-range theories are used in KT activities and can focus on changing health professionals’ behaviours at the level of the individual, group, or organization (Rycroft-Malone and Bucknall, 2010).

### Conceptual framework

Conceptual frameworks differ from theories in that they inform or guide practice, versus predicting practice (Rycroft-Malone and Bucknall, 2010). Examples of conceptual frameworks applied to KT evaluations are the Promoting Action on Research Implementation in Health Services (PARiHS) framework (Kitson et al., 1998) and the Knowledge to Action (KTA) framework (Graham et al., 2006).

### Model

Models are more specific about the relationships that should be expected between concepts in the model (Rycroft-Malone and Bucknall, 2010). The Ottawa Model of Research Use (Logan and Graham 1998) is an example of a KT model. In the following

section, five theories, frameworks, and models that can be used to guide and explain KT implementation strategies are described.

## KT theories, frameworks, and models

### Diffusion of innovations

In his classic and oft-cited work, first published in 1962, Rogers (2003) describes a theory that seeks to explain the process and rate of spread of an innovation (new ideas or technology) within a social system. The theory defines four main factors that are influential in the process of innovation diffusion: (1) the innovation itself (referring to the idea, the practice or the object that is new); (2) the communication channel (the method used to inform others of the innovation); (3) time (the time taken for an individual to make the transition from first knowledge of the innovation to its acceptance or dismissal); and (4) the social system (those involved in decision-making about adoption of the innovation). According to Rogers, diffusion is a process whereby ‘(a) an innovation (b) is communicated through certain channels (c) over time (d) among the members of a social system’ (2003, p. 11). According to the theory, individuals progress through five stages in the process of decision-making about innovation adoption: (1) *knowledge*—acquiring an awareness and understanding of the innovation; (2) *persuasion*—the stage of forming an opinion about the value of the innovation; (3) *decision*—the process of making a decision about adoption or rejection of the innovation; (4) *implementation*—the act of using or applying the innovation in practice; and (5) *confirmation*—reflection upon the decision to adopt or reject the innovation, which may lead to a reversal of the decision.

Rogers (2003) suggests that individual (adopter) and setting characteristics influence the rate and extent of diffusion of an innovation. He defines five adopter categories according to the relative speed of uptake of an innovation:

1. *Innovators*, also described as venturesome, have an interest in new innovations and are responsible for introducing the new idea to the system.
2. *Early adopters* readily adopt the new idea, provide advice and information about the innovation to others within the social network, and assist in hastening the diffusion process.
3. *Early majority* adopt the new idea following a period of decision-making, and prior to the average member of the system adopting the initiative.
4. *Late majority* cautiously adopt the new idea once most other members of the system have embraced the innovation.
5. *Laggards* who possess somewhat traditional values and are suspicious of new ideas are the last members of the system to adopt the innovation.

A critical mass is achieved when enough individuals have decided to adopt the innovation that its continued adoption becomes self-sustaining.

With respect to the innovation, several characteristics are considered important to adoption, including the innovation’s relative advantage (the extent to which the innovation is perceived as superior to existing practices or technologies), compatibility (the extent to which the innovation is perceived as compatible with existing

values, practices and resources), complexity (perception of the ease with which the innovation can be understood and used), trialability (the ease with which the innovation can be trialed or tested), and observability (the extent to which the innovation and its effects are visible) (Rogers 2003).

In the health literature, Roger's (2003) diffusion of innovation theory has been highly influential and has generally been assumed to represent, or be synonymous with, the theoretical underpinnings of research utilization or KT. However, according to Estabrooks et al. (2006), this assumption is yet to be rigorously tested. Voepel-Lewis et al. (2008) used diffusion of innovation theory to assess the clinical utility of three tools designed to assess pain in children in order to determine which tools were more likely to be adopted in clinical practice. The attributes (complexity, compatibility and relative advantage) of the revised-Face, Legs, Activity, Cry, Consolability (r-FLACC) tool (Malviya et al., 2006) and the Nursing Assessment of Pain Intensity (NAPI) (Schade et al., 1996) instrument rated most favourably, when compared with those of the Non-Communicating Children's Pain Checklist-Postoperative Version (NCCPC-PV) (Breaux et al., 2002).

### Theory of planned behaviour

The theory of planned behaviour (TPB) is a social cognitive theory where certain stimuli trigger cognitive processes (thinking), which in turn influence an individual's behaviour. Thus, the TPB, which is based on the theory of reasoned action (Ajzen and Fishbein, 1980; Fishbein and Ajzen, 1975), seeks to predict and explain individual behaviour under certain conditions (Ajzen, 1991). *Intent* of the individual to behave in a certain way is central to the TPB. Intention is assumed to reflect factors that motivate behaviour and the strength of the individual's willingness to behave in a certain way; the greater the intent the more likely it is that the behaviour will be exhibited (Ajzen, 1991). However, the decision to behave in a certain way must be within the individual's *control* (i.e. opportunities for the behaviour must exist and resources, such as time and skills to enable the behaviour, must also be available). Thus, carrying out the behaviour is a function of the opportunities, resources, and the individual's intention to act. The concept, *perceived behavioural control*, refers to an individual's perception of the degree of difficulty associated with behaving in a certain way. This concept is an important element in the TPB, and differentiates it from the theory of reasoned action. The TPB proposes that intention to act and perceived behavioural control are direct predictors of an individual's behaviour (Ajzen, 1991). The strength of an intention to act or behave in a certain way is determined by the individual's *attitudes towards the behaviour* (based on their beliefs about, and evaluation of, the consequences of the behaviour), *subjective norms* (beliefs about what others think about the behaviour), and *perceived behavioural control*. According to the theory, behaviour change requires a change in intentions, which in turn requires a change in the beliefs that support the intention or the introduction of new beliefs (Fishbein and Ajzen, 1975).

The TPB has been used to study the cognitive processes that motivate individual health professionals to incorporate research findings into their practice (Eccles et al., 2007; Perkins et al., 2007). Some researchers have found evidence in support of the predictive ability of the TPB constructs (Eccles et al., 2007; Perkins et al., 2007). These findings indicate that consideration of attitudes towards the behaviour, subjective norms and perceived behavioural

control in the development of interventions to promote the uptake of research evidence in practice might contribute to the success of such interventions. Edwards et al. (2001) used the TPB to identify determinants of nurses' (including paediatric nurses) intention to administer opioids for analgesia. Attitudes, subjective norms and perceived control predicted nurses' intention to administer opioids to patients experiencing pain, accounting for 39.1% of variability in intention ( $F(4, 441) = 708, p < 0.01$ ).

### Promoting Action on Research Implementation in Health Services (PARiHS) Framework

PARiHS is an interactive, multidimensional KT framework. Successful implementation of evidence into practice is defined as a function of sources of evidence used to support a practice change, the practice context and strategies to facilitate change (Kitson et al., 1998). Successful implementation occurs when the research evidence, practice context in which the change occurs, and facilitation strategies used to promote change are 'high' on the utilization continuum (Kitson et al., 1998; Rycroft-Malone et al., 2002). Elements of the framework (i.e. evidence, context, facilitation) were identified in a theoretical analysis of four case studies (Kitson et al., 1998). Further refinements to the framework were made through concept analyses of the three PARiHS elements (Harvey et al., 2002; McCormack et al., 2002; Rycroft-Malone et al., 2004). Rigorous, relevant and generalizable quantitative and qualitative research evidence such as systematic reviews of, for example, effective pharmacological (e.g. Stevens et al., 2013) and non-pharmacological interventions for procedural pain in infants (Pillai-Riddell et al., 2011) are rated 'high' on the evidence to practice continuum (Rycroft-Malone, 2004; Rycroft-Malone et al., 2004). Knowledge from clinical or practice-based experience and patient experience is considered 'high' on the evidence continuum when it is reflected upon, and viewed as relevant (Rycroft-Malone, 2010). Local data/information collected from the practice context is considered 'high' on the evidence to practice continuum when these data are evaluated and interpreted as relevant (Rycroft-Malone, 2010).

Context refers to the environment where pain practice change occurs (Kitson et al., 1998; McCormack et al., 2002). A receptive context includes supportive networks, available resources (e.g. human, financial resources), and initiatives that are consistent with an organization's strategic plans (Kitson et al., 2008; Rycroft-Malone, 2010). Culture, leadership and evaluation are sub-elements of context. Culture is referred to as 'the way things are done around here' (Drennan, 1992). Culture is considered 'high' on the continuum within a supportive learning environment that includes collaboration/teamwork, and decentralized decision-making (McCormack et al., 2002; Rycroft-Malone, 2010; Rycroft-Malone et al., 2004).

'High' leadership occurs when transformational leaders enable, and empower health care professionals to share a common vision by establishing clear roles, and promoting teamwork and decision-making (McCormack et al., 2002). Evaluation and feedback regarding practice change at the individual, team, and system levels are effective when strategies such as performance audits or feedback from health professionals are incorporated into the practice change process (McCormack et al., 2002).

Facilitation is defined by enabling or making easier, the translation of evidence into practice (Harvey et al., 2002). The facilitation process occurs on a continuum where the purpose or role includes low intensity, episodic contact (task oriented), to high-intensity

roles (holistic oriented) that enable individuals to achieve their goals or practice changes (Harvey et al., 2002). Facilitators can be internal or external to an organization and are usually appointed to their role (Harvey et al., 2002; Rycroft-Malone et al., 2002). Facilitation is considered 'high' on the knowledge to practice continuum when appropriate supports are utilized, and when task and enabling skills are applied based on the needs of the practice change (Harvey et al., 2002). Kavanagh et al. (2010) applied the three elements from the PARiHS framework to explain the effects of an organizational KT intervention, appreciative inquiry (AI) to improve nurses' pain practices in a paediatric setting. Twelve nurse facilitators focused on improving evidence-based pain assessment documentation in a paediatric surgical unit. The AI process was viewed as a positive approach to change; however, change overload, logistics, busyness of the unit, and lack of organized follow-up within the practice context were barriers to the intervention implementation. Application of the PARiHS concepts in this study provided further support for the elements of this framework (Kavanagh et al., 2010).

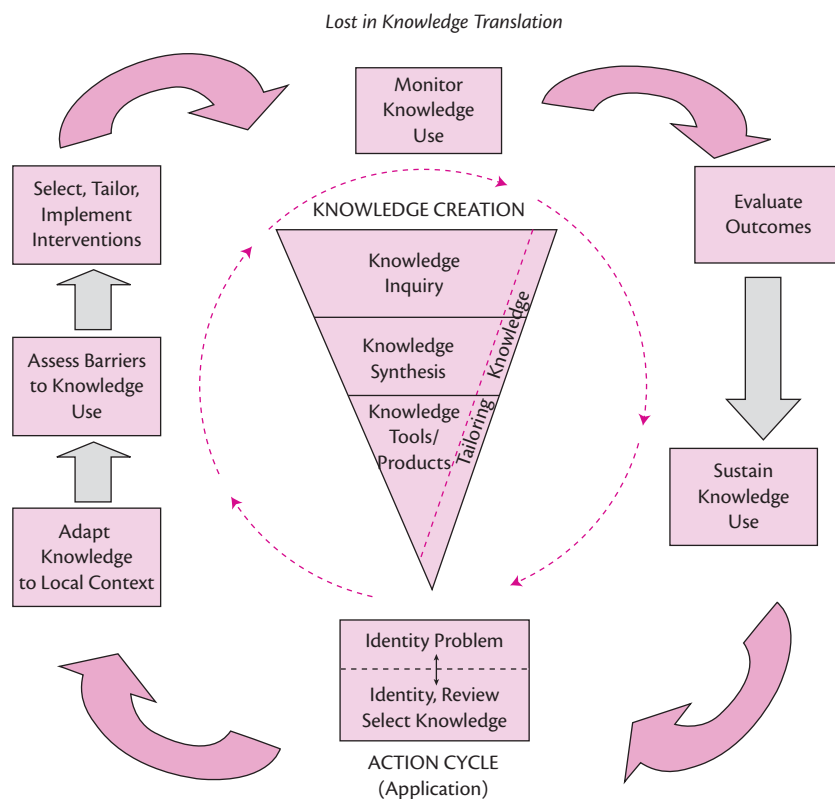

In a study by Stevens and colleagues (2011), three key themes described health professionals' opinions related to factors that facilitated or hindered pain practices in the neonatal intensive care unit: (1) the culture of collaboration and support for evidence-based pain practices; (2) threats to autonomy when making decisions about pain practices, and (3) complexity in delivering pain care (Stevens et al., 2011). The authors used sub-elements of context from PARiHS to explain the study results. For example, in the PARiHS framework, practice cultures that did not value individual's judgements were considered threats to autonomy and therefore were barriers to successful implementation of evidence into practice (Stevens et al., 2011).

## The Knowledge to Action (KTA) Framework

The KTA framework is a systems focused framework that can be used to guide health professionals to change their practice (Graham and Tetro, 2007; Graham et al., 2006). The KTA framework includes a knowledge creation component and an action cycle (Figure 61.1). This iterative, interactive framework also includes an assessment of the local context and culture when planning the implementation of evidence into practice.

The knowledge creation process funnel includes three phases: (1) knowledge inquiry; (2) knowledge synthesis of best evidence, and (3) development of knowledge tools/products. At each phase of the knowledge creation process, knowledge or evidence is further synthesized for the knowledge user. During the knowledge creation phase, knowledge producers identify potentially relevant evidence. Synthesis of best evidence involves generation of systematic reviews and meta-analysis of existing knowledge. Evidence-based clinical practice guidelines and decision aids are examples of knowledge tools/products created during the third phase of the knowledge creation process. Knowledge tools/products such as clinical practice guidelines can then be implemented during the action cycle. All phases of the knowledge creation process can be tailored to the needs of the knowledge user. The knowledge creation process can be used to inform each step in the action cycle, as noted by the dotted lines surrounding the knowledge creation funnel.

The action cycle refers to activities required to implement knowledge or evidence into practice and is based on 31 planned action theories that focus on changing how individuals practice within a social system (Graham and Tetro, 2010). The action cycle consists of seven phases: (1) identifying the problem, identifying, reviewing and selecting knowledge to translate into practice; (2) adapting/tailoring knowledge to the practice context; (3) identifying barriers and

**Figure 61.1** Knowledge to Action (KTA) Framework. Reprinted with permission from Ian D. Graham et al., *Lost in knowledge translation: Time for a map?* *Journal of Continuing Education in the Health Professions*, Volume 26, Issue 1, pp. 13–24, Copyright © 2006 Wiley Periodicals, Inc, <http://onlinelibrary.wiley.com/journal/10.1002/%28ISSN%291554-558X>.

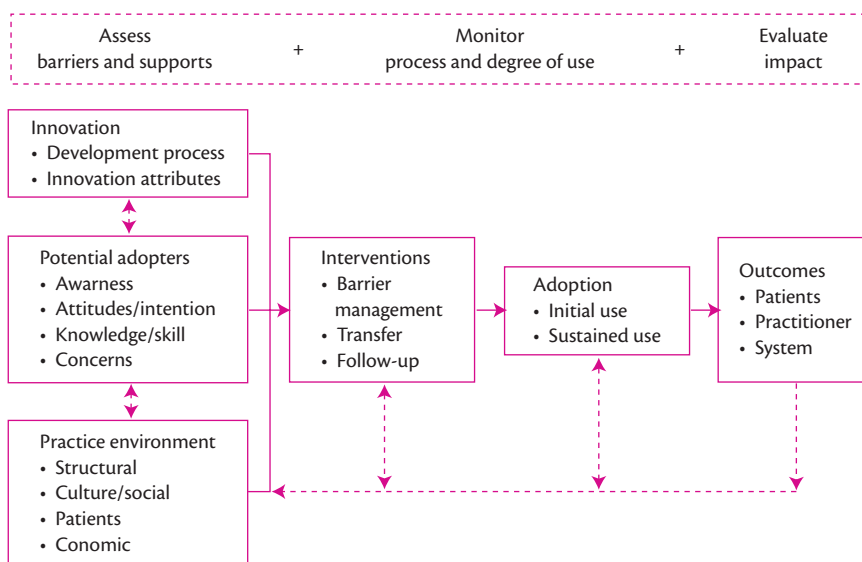

facilitators to knowledge use; (4) selecting, tailoring and implementing KT interventions; (5) monitoring knowledge use such as changes in knowledge and attitudes; (6) evaluating health, health care provider and system-related outcomes, and (7) identifying strategies to sustain knowledge use or a practice change (Graham et al., 2006). The steps within the knowledge to action process are not necessarily sequential. For example, identification of new barriers to practice changes might occur, thus requiring revisions to KT strategies. To date, the KTA framework has not been cited in published paediatric pain research. However, Bandstra (2007) uses components of this framework to describe how translation of evidence-based paediatric psychological pain management interventions (e.g. distraction) could be achieved. In the knowledge creation cycle, Bandstra (2007) emphasizes the importance of developing clinically meaningful and cost-effective psychological pain management interventions. In the knowledge application or action cycle, a multidisciplinary approach to delivering psychological pain management interventions using the steps outlined in the KTA framework is recommended.

### Ottawa Model of Research Use

The Ottawa Model of Research Use (OMRU) is an interactive, planned action model of change (Logan and Graham, 1998, 2010). The OMRU includes six elements that are assessed, monitored and evaluated prior to, during and after KT interventions have been implemented: (1) evidence-based innovation; (2) potential adopters; (3) practice environment; (4) knowledge translation (KT) strategies to translate evidence into practice; (5) adoption and use (both initial and sustained) of the evidence, and (6) outcomes (Logan and Graham, 1998, 2010) (Figure 61.2). The elements of this model are grounded in Rogers' (2003) diffusion of innovations theory, and health behaviour change. Barriers to and facilitators of research utilization are identified in the first three elements and are used to develop and guide the intervention. The OMRU has been applied at the level of individuals, teams, organizations, and healthcare systems (Graham and Logan, 2004).

There are several assumptions about the KT process that are inherent in the model. First, elements of the OMRU are based on an interactive approach, where KT is achieved through collaboration between individuals (i.e. researchers and health professionals; Denis et al., 2004; Graham and Logan, 2004). Secondly, patients and families are integral to the KT process. Finally, aspects of the practice environment influence the process of adopting evidence (Graham and Logan, 2004). Logan and Graham (2010) propose that additional theories could be applied to the elements of the OMRU.

The innovation refers to a new guideline, policy, or procedure that would be implemented into practice, and it should be evidence-based. The innovation attributes refer to the potential adopters' perceptions of the relative advantage, complexity, fit, and feasibility of the innovation (Logan and Graham, 2010). Potential adopters refer to health professionals, patients, and parents who may adopt the innovation. Four sub-elements include: (a) awareness of the innovation, (b) knowledge and intention to adopt the innovation, (c) knowledge and skill required to implement the innovation, and (d) concerns about the innovation or practice change (Logan and Graham, 2010). The practice environment includes four sub-elements: (a) structural factors including decision-making structure, policies, practice standards, physical structure of the practice environment, workload, and current practice; (b) culture/social factors including local politics, leadership, peer opinion; (c) patients; and (d) economic factors including available resources (Logan and Graham 2010). Interventions/KT strategies are tailored to the needs of potential adopters. Interventions are described within three sub-elements: (a) barrier management strategies to promote adoption of the innovation; (b) transfer strategies used by facilitators to train potential adopters, and (c) follow-up strategies to ensure uptake and sustainability of the innovation. A series of steps are used in the adoption process including testing the innovation and sustaining its use. Success of the innovation is measured by patient, health professionals, and system outcomes.

### Case example

The following example illustrates application of the elements of the PARIHS framework to guide implementation of a KT intervention to improve pain practices in infants. The Evidence-Based Practice for Improving Quality (EPIQ), an interactive KT intervention developed by Lee et al. (2009), has been shown to improve health professional practices in relation to reducing nosocomial infection and chronic lung disease in NICUs (Lee et al., 2009). Continuous quality improvement methods that incorporate Plan-Do-Study-Act (PDSA) cycles are embedded within the EPIQ intervention. Stevens et al. (2011) recently applied a more tailored version of EPIQ to improve paediatric pain practices in medical, surgical and critical care hospital units across paediatric tertiary care centres in Canada. The EPIQ intervention consists of two phases: in the first phase of EPIQ, known as the Preparation Phase, a multidisciplinary group of health professionals known as the Research Practice Council (RPC) are identified as *facilitators* of the practice change(s). These individuals review sources of *evidence* to highlight a research or evidence-to-practice gap. The implementation and change phase is the second phase of EPIQ whereby the RPC introduces evidence-based KT strategies to encourage health professionals to modify their current practices.

### Evidence

During the Preparation Phase, RPC members in a neonatal intensive care unit (NICU) evaluated the units' pain assessment and management practices by evaluating *local evidence* in the form of a chart audit. A review of medical charts prior to the intervention indicated that pain assessment using the Premature Infant Pain Profile (PIPP; Stevens et al., 1996) was documented in patient charts only 15% of the time. RPC members and health professionals confirmed a need to improve pain assessment practices in the unit. A recent systematic review supported the strong psychometric properties of the PIPP to assess procedural pain in infants (Stevens et al., 2010). Therefore, local evidence, clinical evidence and research evidence contributed to identifying gaps and supporting evidence-based pain practices. The RPC aimed to improve pain assessment documentation using the PIPP to 50% over the following 6 months.

### Facilitation

In the second phase of EPIQ, the RPC, as *facilitators* of practice change, implemented evidence-based KT strategies to improve use and documentation of the PIPP. The RPC members were individuals who, in accordance with the requirements of the PARIHS framework, have the skills and ability to assist individuals, teams, and organizations to translate evidence into practice (Rycroft-Malone, 2010). The RPC engaged in task-based activities by organizing educational sessions for staff nurses on how to use and document the PIPP. Posters were situated in patient rooms to remind health professionals to assess and document pain intensity scores for their patients using the PIPP. Additionally, the RPC used a holistic approach to improving pain assessment practices by empowering unit staff to reflect on the KT strategies implemented and to participate in tailoring strategies based on the needs of the unit.

### Context

During the implementation of KT strategies to improve pain assessment practices, pain became a hospital wide priority and a component of the hospitals' strategic plan. Senior medical and nursing staff in the NICU began to discuss PIPP pain intensity scores and pain management strategies during daily patient rounds. These *transformational leaders* contributed to change in pain assessment practices at the local level. Staff were updated at regularly scheduled unit workshops that included education on pain assessment. Creating an awareness of the importance of pain assessment contributes to a *receptive practice context* for change. As part of the EPIQ implementation process the RPC, supported by the unit educator, evaluated the practice change by conducting regular practice audits; the results of which were fed back to the unit. A 6-month audit showed that documentation of PIPP scores had improved from 15% to 75%. The practice aim was achieved and pain assessment using the PIPP became part of unit *culture* over time.

An initial assessment of the potential barriers and facilitators, potential adopters and the practice environment is required prior to implementing the intervention. Ongoing monitoring of the intervention implementation and degree of adoption will contribute to tailoring of the intervention to achieve the desired outcomes. The impact of the innovation is measured by evaluating patient, practitioner and system outcomes.

Ellis and colleagues (2007) implemented and evaluated a comprehensive pain management programme (CPMP) to improve paediatric nurses' pain practices with hospitalized children. A nursing management team developed a 4 h pain education workshop that focused on pain assessment and management strategies and they, along with pain resource nurse champions, implemented the CPMP components using various modes of delivery, including email, newsletters, information pegboards, and audit and feedback. The OMRU was used to guide, monitor and evaluate the implementation of the CPMP. The authors monitored nurses' adoption of pain practices by evaluating process outcomes that included aspects of the practice environment, nurses' pain assessment and management knowledge, attitudes and skill, and KT strategies used to promote pain practices. Practice outcomes were measured using pain audits pre and post intervention implementation. Focus groups were used to identify barriers, facilitators and factors that influenced implementation of the CPMP. Statistically significant improvement in nurses' perceptions about the adequacy of their pain assessment ( $p < 0.004$ ), and management ( $p < 0.017$ ) practices were noted as well as statistically significant improvements in use of pain measures ( $p = 0.005$ ) and pain assessment narratives ( $p < 0.01$ ).

## Implications for practice and education, research, and theory

### Evidence-based KT strategies

Evidence-based KT strategies can facilitate integration of pain evidence into practice. For example, the use of reminders to promote health professionals' use of guidelines has been shown to produce small to moderate improvements in care (Grimshaw et al., 2004; Prior et al., 2008). Audit and feedback alone or in combination

with other strategies has been shown to have small but important effects in health care professionals' practices (Ivers et al., 2012). Educational strategies, specifically educational outreach, have been shown to result in small to moderate improvements in patient care (Cochrane Effective Practice and Organisation of Care Review Group, 2002; Grimshaw et al., 2004; Prior et al., 2008). Local opinion leaders (e.g. health care professionals who are members of the unit pain committee), alone or in combination with other interventions, may also facilitate the integration of evidence into practice (Flodgren et al., 2011).

### Understanding the context of practice

The context of healthcare has been conceptualized in different ways, ranging from the physical environment, as the most basic conceptualization, to more complex definitions such as that proposed by French: 'the organisational environment of health care, composed of physical, social, political, and economic influences on the practical reasoning and choices of practitioners about how clinical issues are address' (2005, p. 174).

Over the past 20 years, studies conducted in several countries to examine the barriers to use of research in practice have consistently highlighted the importance of time to implement change, time to read research, the nurse's authority to change practice, reporting of understandable statistical analyses in the research literature, and accessibility of relevant literature, as the most prominent barriers to KT (Carlson and Plonczynski, 2008; Hutchinson and Johnston, 2006; Kajermo et al., 2010). KT initiatives should, therefore, take into consideration the potential for such barriers to impede uptake of pain evidence within the specific practice context and incorporate strategies to minimize or overcome them.

While much of the early work in the field of KT focused on characteristics of the individual and the research itself, it has become increasingly evident that the context in which knowledge is used is another important ingredient in the KT equation. In particular, evidence that research is adopted at different rates and with different levels of success in different contexts has highlighted the importance of context. In light of empirical evidence to indicate that context can influence the success of KT (Cummings et al., 2007, 2010), it is essential that a careful assessment is undertaken of the paediatric healthcare context in which pain evidence is to be implemented. Strengths and weaknesses in contextual characteristics can then be taken into account; capitalizing on the strengths and implementing strategies to overcome or reverse the weaknesses. As well as identification of potential barriers or challenges, an assessment of the receptiveness or readiness of the context to change is important. Meetings with key stakeholders (including health professionals, administrators, educators and children and families) may be helpful in revealing issues and concerns that should be taken into consideration.

Several measures have been developed for health professionals and researchers to evaluate the practice context. Kitson et al. (2008) developed a practical diagnostic assessment tool (which complements the PARiHS framework) to inform development of an implementation strategy. The tool is designed, to help identify aspects of the current environment or context that need to be addressed in order to optimize KT. An aggregated score can be plotted on an evaluative grid to enable visualization of the level of facilitation support required to optimize implementation. The Alberta Context Tool (ACT) (Estabrooks et al., 2009), based on elements from the

PARiHS framework, consists of eight concepts that are used to measure organizational context in healthcare settings. The ACT has been validated in a sample of eight paediatric hospitals that participated in the Translating Research on Pain in Children (TROPIC) study (Stevens et al., 2008–2012) (Estabrooks et al., 2011). McCormack and colleagues (2009) have developed the Context Assessment Index (CAI), also based on the PARiHS framework, to provide health professionals with a tool to assess their practice context and readiness for use of evidence in practice. Testing of this instrument in paediatric settings has not yet been undertaken.

### Promoting and sustaining behaviour change

The tendency for health professionals to adhere to tradition and rituals and to become automated in their practice (Kerfoot, 1999; Monforto et al., 2012) means that unlearning previously well-entrenched behaviour is necessary in order for them to adopt new evidence and modify their clinical practice accordingly. Documenting PIPP scores 75% of the time in patient charts is an example of a notable improvement in clinical practice. However, sustaining this practice improvement remains a challenge and should be a focus of future research

Creating opportunities for interactive sharing of new knowledge, peer review, and dialogue and debate about how evidence could be incorporated into practice, are strategies that can be used to promote and sustain behaviour change in order to facilitate KT. Additionally, promoting positive attitudes and approaches towards pain assessment practices, engaging health professionals in reflective practice, leadership that includes ongoing support, education, commitment to the practice change and performance evaluation can support and help sustain integration of evidence into practice (Davies et al., 2010).

In summary, a theory-based approach to KT research can be used to guide and plan the study design, data collection methods, and analysis. Additionally, theoretical concepts can be used to explain study results and strengthen the construct validity of the specific theory, conceptual frameworks, and models used. Further, evidence-based KT strategies (i.e. educational strategies, reminders, audit and feedback) can be used to promote pain practice changes.

## CHAPTER 62

# Organizational systems in paediatric pain

Mark Embrett and Norman Buckley

### Introduction

Over the past 20 years there has been growing recognition that paediatric pain management can be delivered in a variety of forms, and may be best delivered in a multidisciplinary setting with a shared responsibility amongst diverse health providers, who traditionally have worked independently from each other or at best in parallel. (Desparmet, 2009; Dowden et al., 2008; Weisman, 2008). The composition, size, and organization of a paediatric pain management team can differ based on the number and type of patients served, as well as the organizational structure of the health care centre (hospital, clinic, community health centre, etc.). There is no one 'right' way to organize the team, but diligence is needed when planning a multidisciplinary delivery method. This chapter presents some of the considerations relevant to organizations that are designing a new team, modifying a current arrangement, or assessing the performance/needs of an existing team.

Organizational systems should facilitate the care to be delivered. The process of patient referral and triage should be expeditious, the initial assessment process must identify the issues to be dealt with and ensure that optimal management has been carried out for medical, surgical, psychiatric, and other identifiable disorders. The business of the service or clinic (revenue sources, salary support, supplies, and materials) must be considered. The resources (personnel, supplies, programmes) necessary for the care plan must be readily available, organized, and care delivered in an effective manner with monitoring of the effect and revision as necessary.

The chapter first focuses on an overview of the similar elements to approaches of chronic pain, acute pain, and palliative care, concluding with a description of the ideal multidisciplinary pain management approach (MPMA). The chapter then proceeds to review the specific organization and operations of acute pain and chronic pain services, respectively. Finally, research about the expectation of parents when they enter a clinic and importance of accommodating and promoting positive expectations is presented. The patient flow process in acute pain differs from the chronic pain model and is described. The emphasis remains on consistent clear communication among providers and between providers and patient/family.

### Acute pain, chronic pain, and palliative care: common elements of treatment and potential shared resources

All pain in children has the potential to disturb developmental processes. This section reviews the similarities and differences between experiences of and treatment options for acute pain, chronic pain, and palliative care. Acute pain is the result of an identifiable injury, an acute illness, or surgery. Many of the tenets of the multidisciplinary model of chronic pain care also apply to acute pain services; however, the usual course of acute postoperative or postinjury pain is time limited and may resolve with less overt management of the behavioural aspects. Growing awareness of the presence of 'persistent postsurgical pain' in acute care settings does suggest that there should be clearly defined mechanisms in paediatric care for appropriate treatment if pain persists beyond the expected injury resolution. Chronic pain through its persistence has the potential to greatly disrupt social and psychological processes, as the child and their family respond to the pain and their understanding (or lack thereof) of the factors contributing to it. It may be associated with persisting physiological disturbance (e.g. neuropathic pain from diabetic neuropathy or chemotherapy), or it may be a manifestation of behavioural changes arising out of a physiological event now otherwise resolved, or it may represent a behavioural manifestation of distress because of the source of the initial pain (i.e. cancer now resolved?) or a psychological/psychiatric disorder. Pain associated with terminal illness adds additional suffering to a situation already fraught with distress. Whatever the individual situation, the biopsychosocial model of pain presents a very useful theoretical framework in which to consider the organizational structure necessary to provide treatment. Each factor will be operating to a greater or lesser degree in each situation where pain is manifest, and must be considered in the treatment approach.

There are both common and unique elements of care for acute pain management, palliative care, and chronic pain management. For the acute pain situation, in the case of scheduled surgery, preparation will be helpful (child life); treatment will be directed by acute care medical providers—either surgeons or a 'pain service' usually consisting of anaesthesiology and nursing, often advised by a pharmacist, interacting with the surgical and nursing care teams. Illness and injury will

benefit from the developmentally appropriate educational services of child life, well-trained nurses and in some cases technical interventions from anaesthesia. Communication with the child and their family members is important to ensure understanding of the illness or injury itself, and the meaning of pain in the process. Palliative care requires attention to the spiritual aspects of the impending death, as well as necessary and appropriate medical care, analgesia as determined by the process and impact of the pain. The family must also be cared for. When pain has become chronic, one important issue is to ensure that any responsible disease process has been definitively identified and is under optimal medical therapy (Cott, 1987). Since function may have deteriorated significantly during the 'chronification process', return to normal function may not occur without a structured treatment/recovery plan.

Any acute care paediatric treatment facility will require all of these elements—preparation, acute pain control services, counselling and spiritual support, multidisciplinary care—at least some of the time. Surgery requires preoperative preparation and postoperative analgesia. Palliative care requiring counselling, supportive care, and a wide potential range of symptom management is an unavoidable need for any facility treating serious illness and cancer. Even in the absence of a formal chronic pain programme, there will still be situations where children present with persistent pain and behavioural changes. Expertise in the form of at least some specialists with the appropriate training and a network (even if it is a virtual

network of interested colleagues) will be essential to successful treatment. Our description of acute and chronic pain programmes will, it is hoped, identify the necessary elements and suggest some organizational structures and processes which will support best practice care.

MPMA refers to the practice of combining physiological, pharmaceutical, psychological, and sociological therapies at the same time to achieve improvements in outcome. These services have historically been provided in separate locations both within and outside the hospital setting. However since Dr John Bonica first described multidisciplinary treatments being provided together in one setting (Bonica, 1974), the concept has seen considerable growth in the health care arena (Howard, 2003; Reid et al., 2010; Roy, 2008; Weisman, 2008). The type of services offered in a paediatric pain facility depends on the expertise and focus of the practising professionals (McClain, 2000; Weisman, 2008) but the goal should be to achieve a service equivalent to the Multidisciplinary Pain Clinic as defined by the International Association for the Study of Pain (IASP); teaching institutions will target the Pain Centre (International Association for the Study of Pain, 2012) (Table 62.1).

It has become standard for acute and chronic pain management in children to be performed in a multidisciplinary setting (Peng et al., 2007). Pain centres are the largest and most complex facilities and viewed as the ideal (Weisman, 2008). They also require significant resources. Quite often they focus on outpatient services

**Table 62.1** Preferred characteristics of multidisciplinary pain clinics/centres

<p><b>Qualifications</b></p> <p>A variety of health care providers trained to assess and treat physical, psychosocial, medical, vocational, and social aspects of chronic pain</p> <p>It is required to be able to assess and treat both the physical and the psychosocial aspects of children's complaints. Therefore, at least three medical specialties should be represented, one of which should be a psychiatrist or clinical psychologist (see below for other specialties)</p> <p>Be able to deal with a wide variety of chronic pain patients, including those with pain due to cancer and pain due to other diseases</p> <p>Have a consistently adequate number and variety of patients for its professional staff to maintain their skills in diagnosis and treatment</p> <p>All Health care providers should be appropriately licensed and have significant knowledge of both the basic sciences and clinical practices relevant to chronic pain patients</p>
<p><b>Communication</b></p> <p>The health care professionals should communicate with each other on a regular basis both about individual patients and the programmes which are offered in the pain treatment facility</p> <p>Have established protocols for patient management and assess their efficacy periodically</p>
<p><b>Staffing essentials</b></p> <p>Staff can include physicians, nurses, psychologists, physical therapists, occupational therapists, vocational counsellors, social workers, and neurologists</p> <p>Director/Coordinator who will be responsible for monitoring of the medical services provided</p> <p>Administrative/Support staff to maintain records on patients for assessment of individual treatment outcomes and evaluation of overall programme effectiveness, also to carry out additional activities</p> <p>Medically trained professional available to deal with patient referrals and emergencies</p>
<p><b>Services</b></p> <p>Diagnostic and therapeutic services which include medication management, referral for appropriate medical consultation, review of prior medical records and diagnostic tests, physical examination, psychological assessment and treatment, physical therapy, vocational assessment and counselling, and other facilities as appropriate</p> <p>Facilities for inpatient services and outpatient services should be present</p>
<p><b>Research characteristics for a centre</b></p> <p>Carry out research on chronic pain. All providers do not have to do both research and patient care but the institution should have ongoing research activities</p> <p>Actively engage in educational programmes for a wide variety of health care providers, including under-graduate, graduate, and postdoctoral levels</p> <p>Affiliation with a major health sciences educational or research institution</p>

to avoid the cost of inpatient care (Weisman, 2008). There are a variety of terms used to describe multidisciplinary facilities, but the main distinctions lie between multimodal, interdisciplinary, and multidisciplinary. Multimodal treatment refers to the simultaneous application of separate and complementary therapeutic intervention performed under the supervision of a single practitioner (American Society of Anesthesiologists, 2010). The distinction between interdisciplinary and multidisciplinary treatments is less distinct. Traditionally multidisciplinary approaches have been used to describe a plan with more than one provider (usually medical specialists) delivering care without direct communication or collaboration with the other providers, and not necessarily in the same location. An interdisciplinary approach coordinates the providers in one setting (usually including several distinct disciplines including medicine, nursing, psychology, physiotherapy, etc.) so that they work together in an integrated manner and develop joint goals with the patient (Rudin, 2001). Recently, the term multidisciplinary has been used in the research literature, as an umbrella term that refers to both inter- and multidisciplinary approaches (Ospina and Harstall, 2003). This chapter will employ the term multidisciplinary pain care (MPC) to refer to the ideal setting of an interdisciplinary coordinated approach either in a pain clinic or a pain centre.

The International Association for the Study of Pain (IASP) has stated that there is significant evidence for the effectiveness of multidisciplinary treatment for chronic pain. The Canadian Pain Society (CPS) has stated the need to include both physical and psychological treatment elements into patient care. The CPS (2012) position statement states, 'Pain is not just a symptom of underlying illness or injury, but it is a disease in its own right, with significant changes in complex biological, and psychological functions'. This statement emphasizes the requirement to treat pain symptoms holistically, using a variety of providers.

## Acute pain services

Acute pain services need to be available 24 h a day, 7 days a week. Services may be centralized as a formal acute pain service within a health care setting (i.e. hospital), or can be provided by surgical staff, hospitalists, and ward nurses. Either model could provide excellent care. The choice will be affected by the local situation (presence of trained and interested anaesthesiologists and nurses, acceptance by surgeons and ward nurses). Whichever model is used, there should be access to the range of strategies and techniques as described in Box 62.1.

Institutional procedures should be established for education and training, monitoring of patient outcomes, documentation, and institutional monitoring of activities, and availability of service providers (anaesthesiologists, appropriately trained nursing staff or physician assistants). Observational studies have found that education and training programmes for health care providers in pain care are correlated with lower pain levels, decreased nausea, and increased patient satisfaction (Coleman and Booker-Milburn, 1996; Harmer and Davies, 1998). Educational programmes should include content ranging from basic bedside pain assessment to sophisticated pain management techniques, and non-pharmacological interventions. Comprehensive training programmes for all new personnel are required.

There is limited evidence to suggest that monitoring of outcomes and the availability of anaesthesiologists for specialty care in pain

### Box 62.1 Recommended established procedures for acute care models

1. The documentation of the pain history of patient, including: typical pain related behaviours, and the child's description of the pain.
2. Systematic assessment and recording of pain and all related symptoms.
3. Pharmacological management.
4. Cognitive-behavioural management.
5. Strategies to prevent pain and other symptoms.
6. Management of side effects of treatment.
7. Monitoring of pain, vital signs, and level of consciousness.
8. Ensure that all specialized services and techniques provided throughout health centre are available for treatment including: patient controlled analgesia, epidural infusions, patient controlled epidural analgesia, subarachnoid infusions, plexus infusions, implantable baclofen pumps.
9. Education and training programmes.

management improves outcomes, but many paediatric health practitioners agree that these are key features to be included in any acute pain service (American Society of Anesthesiologists, 2010). There is also strong agreement that in light of their expertise and training, anaesthesiologists should be involved, along with other health care providers, in the establishment of all acute pain guidelines, treatment standards and practices.

The acute pain service is a model in which a recognized group of health care providers (physicians, nurses, and pharmacists) are responsible for the development of standards for pain assessment and management throughout the health centre. There is evidence that this type of service model provides more prompt care (Miaskowski et al., 1999). This group has as its primary goal the delivery of hands on care and symptom management on a daily basis for a specific cohort of patients (Berde and Solodiuk, 2003). Advantages of this approach are that there is a dedicated team that have pain management as their sole focus not as a secondary goal. The team has expertise and a commitment to be effective and over time their experience grows and they will become a better team, able to handle a variety of situations and possible complications. There is also the potential institutional advantage of a team that the rest of the health centre can quickly contact when needed. This group is positioned to implement quality assurance strategies which contribute to improved care. Disadvantages of this model include possible inhibition of a more general development of health providers' skill beyond basic acute pain management. Providers should be aware that this may happen and develop ways to ensure professional development. In order to keep pace with innovations in other fields (new procedures, surgical techniques etc.), the pain service team should develop communication links with departments throughout the health centre. Finally, there are increased costs associated with developing a specific pain service. It may be difficult to financially justify creating a team of skilled providers for the sole purpose of acute pain treatment (Berde and Solodiuk, 2003).

The alternative to having an acute pain service model is to have primary care or health centre practice standards with educational support. In this setting pain management is implemented by the individual services using standards set by a multidisciplinary committee. Standards are for both assessment and analgesia. Regular education programmes are often provided in this setting (Berde and Solodiuk, 2003). There are several advantages to this approach but implementation requires widespread education and training. It 'empowers' providers practising throughout the health centre, intimately familiar with their patients who can evaluate pain and other symptoms within the context of their overall management. Costs are often lower than in the acute pain service model. A disadvantage is that acute pain care is no one's primary responsibility; providers may be more preoccupied with other aspects of treatment and overlook pain management. It may be unrealistic to expect busy clinicians to continually train and educate themselves on best practices in acute pain management; therefore there is a risk that treatment may not be optimal. There may be more delays in this type of treatment environment, often due to competing tasks. Finally, there may be less intensive monitoring and feedback about treatment, therefore suboptimal practices may not be identified and rectified. There is less risk that losing one or two key providers (advanced practice pain nurses, for example) will disable an entire service, but it takes longer to get all staff up to a high level of performance.

### Preoperative preparation

By reducing the anxiety and distress associated with many commonly performed surgical procedures, long-term treatment outcomes can be improved (Golianu et al., 2000). Preoperative assessment and consultation around analgesic management can significantly alleviate some symptoms of postoperative pain and are critical to pain management (American Society of Anesthesiologists, 2010). The MPC team will discuss with the child and family issues related to the surgical procedure, pain and expected treatment options including: expected severity of postoperative pain, pre-existing medical conditions, risk-benefit of the treatments under consideration, previous experiences with pain, and patient preferences. Preoperative establishment of a pain management protocol is associated with less overall analgesic use, shorter time to extubation, and shorter times to discharge (Susan et al., 1998).

Preparation of the patient includes continuation of usual medications (preventing abstinence syndrome) and premedication needed for the surgery. Educational sessions for the patient and family can include behavioural pain control techniques. Although it is suggested that most of the MPC team, especially the anaesthesiologist, be present during the educational components (American Society of Anesthesiologists, 2012), for practical purposes much of the transmission of information is frequently carried out by child life providers or other professionals, while the anaesthesiologist will provide their input in the context of the preoperative anaesthesia assessment. Patient and parent roles in interpreting postoperative pain should be established before surgery. This will support achieving comfort, reporting of abnormal pain patterns and proper use of analgesics.

### Facilities and equipment for acute pain interventions

Table 62.2 details procedures and their associated equipment and staffing needs (Brislin and Rose, 2005; Golianu et al., 2000; Rusy

and Weisman, 2000; The Royal Australasian College of Physicians, 2006). The majority of these procedures should be available when needed. Organization of staff scheduling should bear in mind the training of available staff during each shift to maintain the availability of these procedures to be performed by highly skilled and trained staff. Several of the methods require more than one trained professional on hand; availability of such a person should be ensured. Training and education about these techniques should be routine in pain management centres.

## Chronic pain management

Paediatric chronic pain has a significant impact on social, emotional, psychological, mental, and spiritual components of the life of a child and their family. The biopsychosocial model of pain provides the essential theoretical framework within which to establish a treatment programme. Delivery of care in all three areas must be provided by the organizational structure.

Three key features of the insidious development of pain from first occurrence to life changing condition have been described: impairment, disability, and handicap (Desparmet, 2009). *Impairment* is when the pain first surfaces and begins a cycle of pain-inactivity-more pain-more inactivity. This leads to *disability*, when a child is unable to physically participate in age-appropriate daily activities. Parents often identify behaviour changes and absenteeism from school and other structured activities. The physical separation from family and peers is accompanied by emotional isolation. These psychological and mental consequences often lead to *handicap*, characterized by sleep disturbance, further emotional withdrawal, and expressions of hopelessness. This may severely limit the normal development of the child. As described, chronic pain has significant far reaching negative repercussions on the child's life. Therefore treatment must address all of these concerns and should be a priority for the family. Early intervention, with the aim of limiting the duration or extent of disability, will hopefully prevent major impairment. The objective of a pain management programme may in fact be a return to normal functioning, and not resolution of pain symptoms. Paradoxically, return to function can often lead to reduction in pain (Desparmet, 2009).

Before patients enter a Paediatric Pain Centre (PPC) they have often visited a variety of other specialists over a period of 4 to 6 months and have not observed substantive positive results. This fragmentation of care exacerbates the *disability* process (Desparmet, 2009). Additionally the family is often required to restructure their daily routine and possibly their employment patterns. This disrupts the life of both the patient and their familial support system.

This paediatric MPC includes the composition of the health provider team and their individual and cumulative backgrounds as essential in developing a MPC team. Furthermore their consistent communication and progressive development is highlighted as a key to success. Paediatric chronic pain is positioned as a biopsychosocial phenomenon that requires the involvement of patient, their family, their social support, and the experiences, attitudes, and beliefs that they bring to the assessment period and through treatment. The expressed symptoms and biological determinants are considered in conjunction with medical guidelines and pathology and incorporated into the framework of the social and psychological characteristics of the family and patient. Mental health history, lifestyle, education, social patterns, stressors, and any related family

**Table 62.2** Techniques and equipment for acute pain services

Technique	Personnel	Equipment
<b>Distraction</b>	Any health professional or family member	Materials that can capture and maintain a child's attention Kaleidoscope Stories Bubbles Counting Pop-up toys Video games
<b>Deep breathing/muscle relaxation</b>	Physical therapist, psychologist, nurse, or family member with some education on the process	None
<b>Self-regulation</b>	Nurse, psychologist	Biofeedback equipment Transcutaneous electric nerve stimulation unit
<b>Topical anaesthesia</b>	Anaesthesiologist, nurse, or physicians able to record the process (dose, medical history)	None
<b>Local infiltration</b>	Anaesthesiologist, nurse, or physicians able to record the process (dose, medical history) Must be competent in CPR	Smallest gauge needles required Correct drugs and dosage
<b>Peripheral nerve blocks</b>	Anaesthesiologist, nurse, or physicians able to record the process (dose, medical history) Must be competent in CPR Provider should be trained in the technique, and be familiar with it A trained assistant should be used to monitor the patient during the procedure	Short-bevelled needles or specific insulated needles for connection to a nerve stimulator Correct drug dose and volume Oxygen supply Equipment for artificial ventilation Suction equipment Defibrillator Cardiac resuscitation drugs.
<b>Bier block (intravenous regional anaesthesia)</b>	Anaesthesiologist, nurse, or physicians able to record the process (dose, medical history) Must be competent in CPR Staff should be trained and familiar with use and complications. A trained assistant should be used to monitor the patient during the process.	Tourniquet Proper drug dose and volume Resuscitation equipment
<b>Nitrous oxide (N<sub>2</sub>O) analgesia</b>	A separate person should be used to administer the N <sub>2</sub> O that is not conducting procedure. Anaesthesiologist is recommended to be present especially if there are any expected complications	A means to separately delivery oxygen and N <sub>2</sub> O Resuscitation equipment
<b>Ketamine and midazolam</b>	Staff should be trained and familiar with use, adverse effects and complications A trained assistant should be used to monitor the patient during the procedure Staff should be trained in advanced airway management	Resuscitation equipment Oxygen supply Equipment for artificial ventilation Suction Defibrillator Cardiac resuscitation drugs

history should be accounted for in order to develop the treatment with highest probability of success. Incorporating at least three health providers into an extended interview with the patient and family will allow for a variety of professional perspectives to interpret the family dynamics, communications patterns, and identify any potential threats that may arise. The team should also determine the capacity of the family to implement treatment. Factors to consider include: marital or financial stress, school absenteeism, family

accommodation, school transition, high performance demands, and relationship-oriented rejection or loss (Desparmet, 2009). For example there is a surprisingly high percentage of patients that are enrolled in demanding course loads, are extremely active in extracurricular activity (sports, music, volunteerism), and have a demand placed on them to perform (Weisman, 2008).

The focus of chronic pain treatment in MPCs is rehabilitative instead of curative. The team should emphasize definable, operable

**Table 62.3** Goals for a MPC paediatric patient and their family

Symptomatic improvement
Improved physical function to participate in activities appropriate for age
Reduce pain sensitivity and intensity
Regain independence appropriate for age
Family and patient master coping techniques
Master self-management skills appropriate for age
Restore individual and family productivity to a satisfactory level
Decrease inappropriate use of health care system

and realistic outcomes for the patient, rather than complete pain relief (Gardea and Gatchel, 2000). Quality of life outcomes with a focus on independence through restoration of physical, psychological, and social functioning (Table 62.3) should be the goal. The rehabilitation plan should be developed on an individual patient basis with all team members. The process of a MPC is illustrated in Figure 62.2, with further detail in the following subsections including the staff, communication, multidisciplinary integrative assessment, outcomes, patient and parent expectations and experiences and follow-up are described later in this chapter.

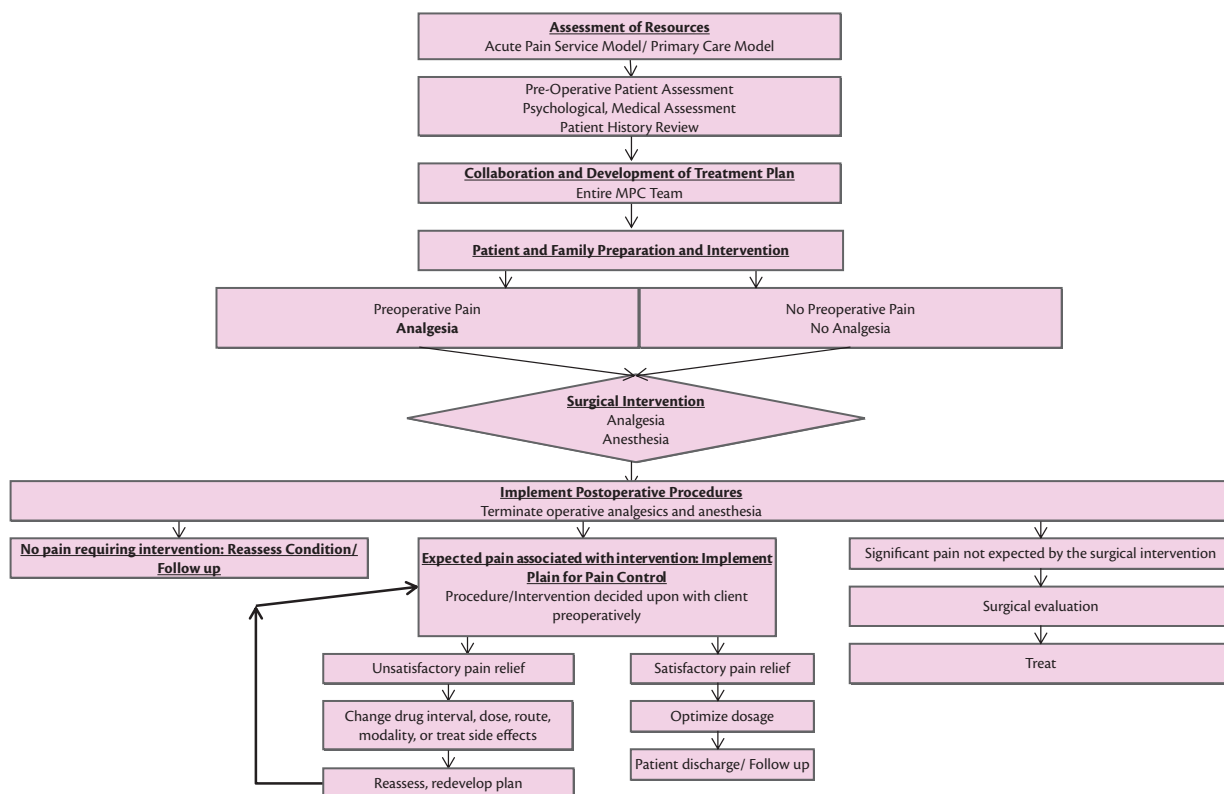

### Staff positions and organization

The disciplines required and services offered by a PPC will be determined in part by the conditions being treated. The most commonly seen chronic pain conditions in PPCs include

headache, abdominal pain, myofascial pain, arthritis, back pain, complex regional pain syndrome, phantom limb pain, cancer pain, sickle cell pain, and cerebral palsy-related pain (Weisman, 2008). A list of staff positions will include some or all of the following: the Director, Physical therapist, Nurse, Physician(s), Anaesthesiologist, Psychologist, Pharmacist, and Child Life Specialist. Their specific roles and skill sets have been well described, as well as the contribution each makes to the overall process through their individual discipline (Berde and Solodiuk, 2003; Cravero and Blike, 2004; Eccleston, 2001; Joseph, 2007; Kingsley and Porfyrus, 2011; McClain, 2000; Palermo et al., 2010; Schurman and Friesen, 2010). Each may fulfil more than one role depending upon resources and skill sets available—for example, anaesthesiologists will have a specific professional role but may also serve as the pain specialist; other physicians may serve to offer services arising out of their personal skill sets or function as speciality consultants (e.g. neurology, physical medicine, surgery, neurosurgery, psychiatry). No matter which medical or other professionals are involved in the care however, the most important overall functional issue is management of the communication process, as described next.

### Staff communication/organizational relationships supporting practice

Although the specific role descriptions of the staff of a MPC team are important, they may be to some extent less relevant to the organizational systems discussion than the manner in which they relate to one another and the programmes offered. Very little specific research illuminates the issue of effective communication

**Figure 62.1** Patient flow for acute care services.

amongst MPC professionals; however consistent communication is essential to the success of the MPC team (Dowden et al., 2008). Figure 62.2 also highlights communication within the MPC team. Many of the professional roles are traditionally independent and training does not always emphasize multidisciplinary collaboration. Routines, protocols, and regularly scheduled meetings should be implemented and encouraged in order to promote effective communication and practice. Nurses, because they can have varied roles, are often the core of effective communication (Berde and Solodiuk, 2003). Nursing research examining the process of incorporating research into practice has identified those characteristics of an organization which will best support implementation of best practice. This is described as the PARIHS (‘Promoting Action on Research in Health Services’) framework (Rycroft-Malone, 2004). Successful implementation of best practice is best supported by: evidence itself, context, and facilitation. These three are further broken down to reflect: evidence—research evidence, clinical experience, patient experience and local data/information; context—culture, leadership, and evaluation; and facilitation—purpose, role, skills, and attributes. The organizational system thus can support this process by ensuring communication of local clinical experience and patient experience as well as providing local data and information, by providing a culture which will support/promote best practice, by selecting leaders who support these goals and putting in place communication systems to facilitate the process, and by training personnel in the skills of facilitation. It can be seen that these elements, while originally developed to address a somewhat different issue, are very relevant to the complex problems which frequently surround management of paediatric patients with chronic pain.

A paediatric chronic pain disorder such as ‘functional gastrointestinal disorder’ (FGID), illustrates the importance of effective communication strategies. It is associated with a complex combination of symptoms, including pain, related to biological and psychological processes. These patients have high levels of health care utilization and incur significant financial costs (Schurman and Friesen, 2010). In this type of multifaceted disorder there may not be established clinical guidelines. Treatment is thus best provided in a multidisciplinary setting in order to enhance outcomes and hopefully decrease long term health care costs. The success of treatments often depends on the integration of the recommendations of the full range of disciplines involved, especially when interventions need to be combined for these complex disorders (see Table 62.4).

Parental expectations

Unlike an adult, a child relies on the caregivers (parents) of the family to make decisions about care. Thus the family must be incorporated into the care process to an even greater extent than in adult pain management. As positive expectations for treatment and recovery on the part of both patients and their families will benefit overall outcome, it should be a goal for the MPC to initially establish an optimistic attitude towards expectations (Long and Guite, 2008). This can be a challenge because the MPC team is rarely the first service parents have sought for the child’s pain. Prior to the visit to the MPC team, families with children suffering from long-term chronic pain have low expectations for MPC (Tsao et al., 2005). This is often the result of prior disappointment as previous diagnosis and treatments have failed to offer relief, which

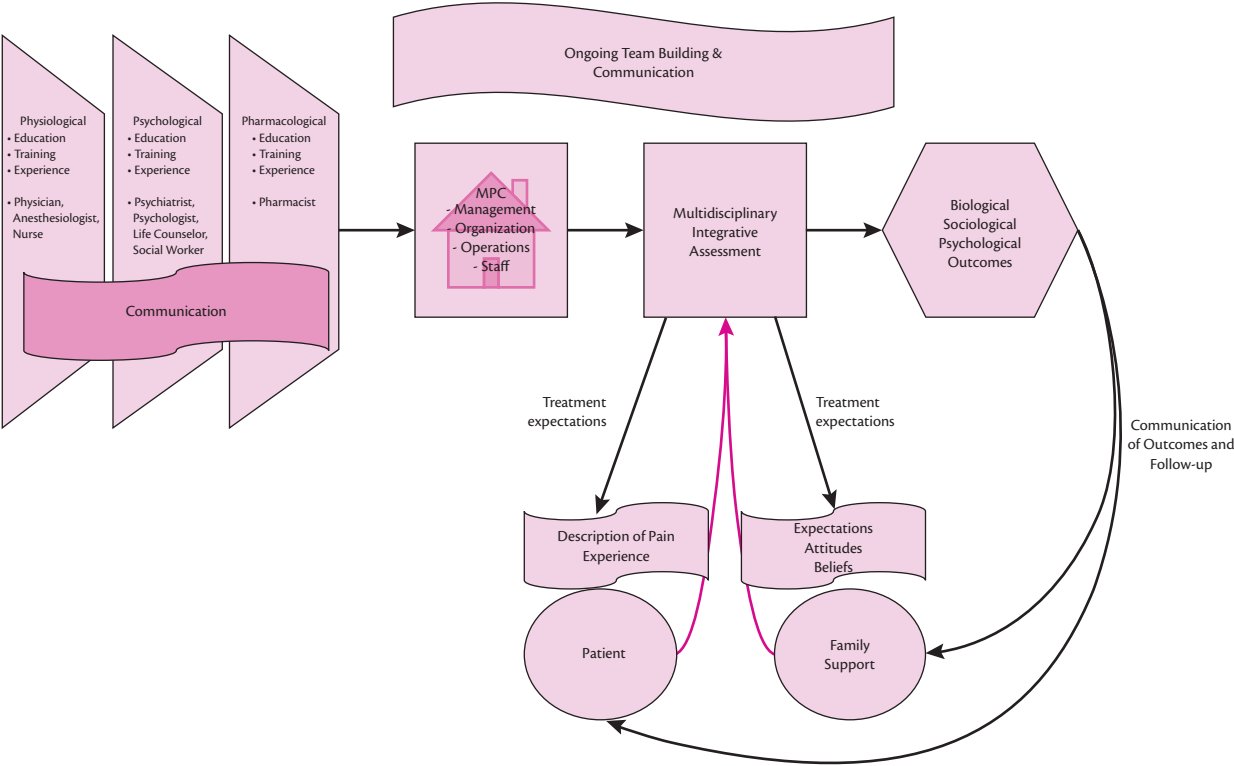

Figure 62.2 Structure and process of a MPC.

**Table 62.4** Examples of biopsychosocial interventions that have been combined for complex disorders

Intervention	Primary roles
Prescription medication	Pharmacist/Physician/Nurse
Biofeedback assisted relaxation training	Psychologist/Nurse
Personalized therapy that targets: school issues, pain coping strategies, sleep hygiene	Psychologist/Life Counsellor/Nurse
Acupuncture	Physical Therapist
Massage	Physical Therapist
Physical therapy	Physical Therapist/Nurse
Family therapy	Counsellor
Sleep evaluation	Psychologist

**Table 62.5** Quotes of parents' perceptions of care at a MPC

Perceptions of the MPC treating the whole body
'Knowing that they are looking at the whole picture, not just 1/4 of it'
'The mind–body connection—having both doctors meet with us together was very helpful'
'Explaining how it's all going to come together to help our son.'
Perceptions of the MPC team
'The process and desire to understand to assist and educate'
'How well the staff worked to make me and my child comfortable and how to assist my child when he has pain'
'People dedicated to getting the problem resolved.'

Text extracts reproduced from Jennifer Verrill Schurman and Craig A Friesen, Integrative treatment approaches: family satisfaction with a multidisciplinary paediatric Abdominal Pain Clinic, *International Journal of Integrated Care*, Volume 10, p 1–9, Copyright © 2010 (CC By 3.0).

results in frustration. However, after the coordinated interdisciplinary assessment, and once treatment plans are developed, parents are often quite appreciative of the service provided in the MPC team, especially with holistic and multidisciplinary team approach (Table 62.5) (Schurman and Friesen, 2010). Many paediatric pain facilities are structured to offer a variety of health care services on the same day as the first visits. This is not only convenient for families but establishes early on that a comprehensive examination of the child's needs is being completed.

Results are not always positive, however, and it is important to recognize when MPCs do not get it right so that these situations can be planned against. If expectations are not met, mistrust and sensitivity to future advice can arise: this represents a continuation of experience of failure derived from previous visits to other single modality specialists (Weisman, 2008). Negative experiences with MPCs include the length of a visit (including time waited between meetings) waitlist times, scheduling conflicts, and complexity of the interpretation of outcomes.

Parents expect the MPC to offer coping solutions and stress management skills (Claar and Scharff, 2007). They also anticipate

receiving information about the cause of pain, treatment options, drugs, and the effects of both the pain and any underlying processes associated with the pain (Reid et al., 2010). This information is expected to be provided as written information to which they can refer later. This can be very important to the parents' perceptions of successful treatment, and may be linked to better adherence. Whenever possible MPC teams should strive to meet these expectations and be aware of any lingering patient or parent doubt. When parents' expectations are not met, treatments of the child's psychological, physical, and social state may not be perceived as completed. This may lead to an extended treatment regimen or relapse of symptoms. Although it is not always the case, positive expectations for recovery are correlated with better health outcomes (Long and Guite, 2008).

## Information management systems

Many centres are moving to implement electronic medical records (EMRs) which may facilitate information management programmes and help the MPC to improve transfer of information between professionals. All clinical charts must be up to date and readily available to any member of the treatment team. Towards this goal, Computerized Clinical Decision Support Systems (CCDSS or CDSS) may promote implementation of best practice care. This is somewhat complex in the sense that in order to effectively have an impact upon care, certain characteristics must be present in the CCDSS. Several systematic reviews (Kawamoto, 2005; Roshanov, 2011) have found that improvement in care could be achieved through implementation of a CCDSS. None of the trials specifically addressed pain care or paediatric pain care in particular, so the applicability and impact cannot be commented upon directly. These have also yet to demonstrate an impact on patient outcomes.

## Patient flow for chronic pain services

Figure 62.3 illustrates the stages of the patient flow through a MPC. The process begins with a referral, either by the patient's general practitioner, another health care provider or health centre. Clinic intake may be defined by diagnosis, duration of the problem or presence of psychological or social comorbidities.

### Initial evaluation

Organization of the data gathering process is important. Cott has argued that the initial interview for a complex problem requires the simultaneous presence of the most senior clinicians; in other programmes initial data gathering may use standardized questionnaires administered by relatively junior clinicians or non-specialists (Cott, 1987). The child should obviously be involved in all decisions (Desparmet, 2009). The evaluation of the patient should involve family members and consider the entire history and family dynamic. Parents should be prepared for the possibility of an extended meeting. A checklist of items that should be discussed during this initial evaluation is provided in Table 62.6 (adapted from National Health and Medical Research Council, 2005). The length of this extended first contact interview can be anywhere from an hour to the better part of a day (Weisman, 2008). Parents and siblings should be incorporated into the interview, which will include social history, school performance and extracurricular activities changes.

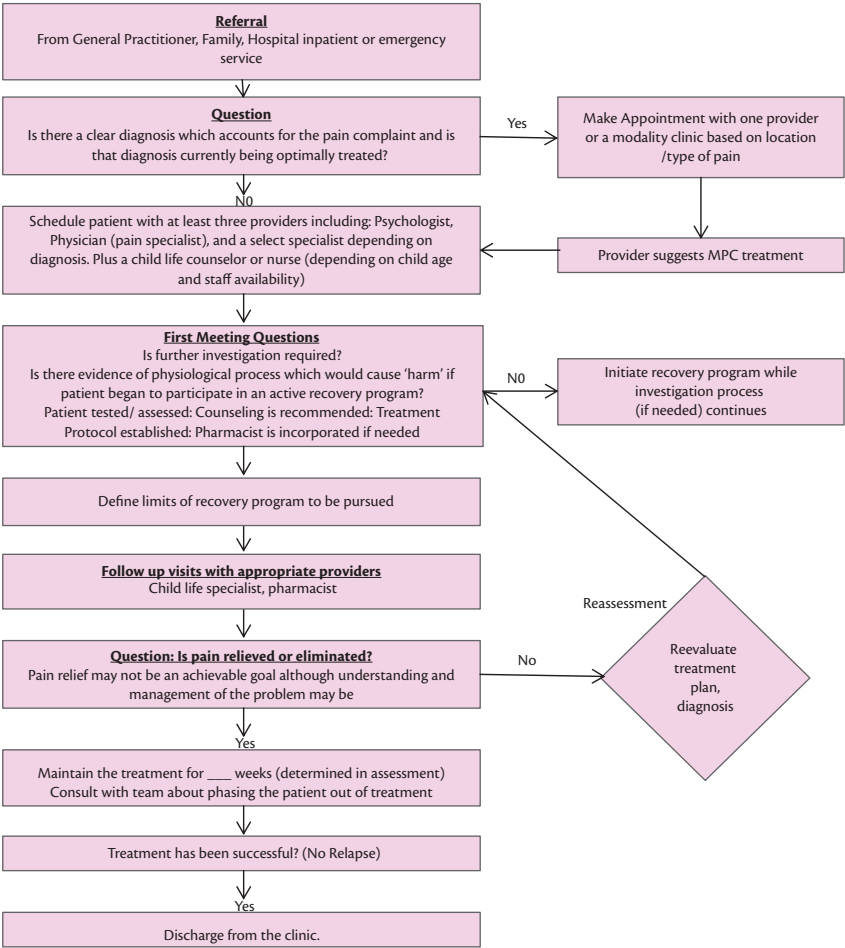

Figure 62.3 Patient flow for chronic care services.

Table 62.6 Patient assessment checklist (conducted with child and family present)

Circumstances associated with pain onset
Primary site of pain
Radiation of pain
Character of pain (throbbing, sharp, aching etc.)
Intensity of pain during movement, at rest, and at present, during last week
Highest level of intensity
Factors altering pain (what makes it worse/better?)
Associated symptoms
Temporal factors (is pain present continuously or otherwise?)
Effect of pain on activities
Effect of pain on sleep
Medications taken for pain
Additional treatments used for pain
Health professionals consulted for pain treatment

Pain history information of significance for symptomatic treatment of pain
Expectations of outcome
Patient belief around cause(s) of pain
Family belief around cause(s) of pain
Expected reduction in pain and symptoms required to resume regular activities
Patient's typical coping response for stress or pain,
Presence of anxiety or psychiatric disorders (e.g. depression or psychosis)
Family expectations and beliefs about pain, stress and postoperative course
Ways the patient describes or shows pain

Source: data from National Health and Medical Research Council, *Acute pain management: scientific evidence*, Sydney, Australia, Copyright © 2005 Commonwealth of Australia.

Physical exam, diagnosis, and feedback

The physical exam including neurological exam (Desparmet, 2009; Weisman, 2008) and the diagnosis and feedback all provide both diagnostic and communication opportunities. Ensure adequate time for understanding, and confirm comprehension (Desparmet,

2009). This is where trust between provider and patient can be reinforced. All questions should be answered thoroughly.

The plan will be multifaceted and complex, and determined by the team during evaluation of the patient's needs and capabilities.

Outcome goals are established in the feedback session, such as reintegration into various aspects of daily routine (Weisman, 2008). Families may not always accept the diagnosis and plan, follow up should be encouraged. If the family is unwilling to return then the importance of a discussion with their family doctor should be emphasized. Refer to the section on parents' perceptions about how to increase their satisfaction which has a highly positive association with adherence and good outcomes.

## Conclusion

This chapter provided guidance and described options for organizations that may adopt a new or modify an existing paediatric pain centre. It focused on the importance of multidisciplinary treatment assessments and the incorporation of the entire health team through various times of the treatment plan. The information here will help identify the proper staff for a MPC, and emphasize the need for team leaders to be explicit with members about procedures and expectations from the beginning. Using options presented, multidisciplinary teams may develop such procedures; however each team may require certain customization. The emphasis should be on team cohesion, which will translate to better patient care. The sections of parental expectation and patient flow may assist teams to communicate clearly with the family about what the patient may expect from treatment and recovery options.

### Case example

MacKIDS is a moderate sized paediatric hospital, contained within a large hospital corporation providing all paediatric services save solid organ transplant and cardiac surgery. It has had a robust postoperative paediatric pain service which functioned as part of the adult service until the adult inpatient surgery relocated, leaving a small paediatric service with 2 h per day of nursing time assigned from amongst the Post-Anaesthesia Care Unit nursing staff.

Recently a community foundation has offered fundraising support directed to establishment of an interdisciplinary pain programme. The community foundation has coordinated a meeting of Canadian paediatric pain experts to identify best practice in a chronic pain programme for paediatrics. They have created a 'made in Canada' approach to the problem intended to be a template for a knowledge translation effort into multiple jurisdictions supporting best practice complex pain care for children, adolescents and young adults transitioning between paediatric and adult care systems. This information is providing a model to guide programme development at MacKIDS.

The question of how to best provide paediatric chronic pain services, acute pain services and possibly also support palliative care services has arisen during a time of health care budget contraction. Awareness of the need for paediatric chronic pain care is growing. It is becoming clear that although the volume might be small, there is a need for an organized institutional approach to paediatric chronic pain care.

The challenge is to identify those elements which can be provided either through re-allocation of existing resources or at the least possible incremental cost.

## CHAPTER 63

# Education for paediatric pain

Alison Twycross and Susan O'Conner-Von

### Summary

This chapter focuses on educating children, parents, and health care professionals about pain management. The first half of the chapter examines issues related to children and parents while the second half concentrates on health care professionals. The current state of knowledge will be explored and strategies for educating each group discussed. The Promoting Action on Research Implementation in Health Services (PARIHS) model (see also Yamada and Hutchinson, Chapter 61, this volume) is used to help explain why healthcare professionals do not always use their knowledge in practice. Implications for practice, education and future research are also outlined.

### Children and parental knowledge about paediatric pain

#### Children's knowledge about pain

It is well established that a child's cognitive development affects their perception of pain, behavioural response to pain, and ability to communicate about pain (Harbeck and Peterson, 1992). A child's view of pain tends to follow a consistent developmental pattern (McGrath, 1990). Children learn about pain and how to cope with pain through their own and their family's experiences with pain. Moreover, the significance of what children learn about pain is a direct result of their stage of cognitive development (Wood, 1993). For example, school-aged children in Piaget's concrete operational stage are able to perform cognitive operations and apply new skills when thinking about events. These children can use their past experiences to understand the reasons for administration of an analgesic drug.

Most paediatric pain research exploring the educational needs of children has focused on procedural pain. Children often consider procedures to be worse than the health issue initiating the need for the procedure (Finley and Schechter, 2003). The most commonly studied needle procedures are immunizations and injections. A systematic review of psychological interventions for needle-related procedural pain in children (28 randomized controlled trials with 1951 participants) included children aged 2 to 19 years (Uman et al., 2010). Distraction, hypnosis, and combined

cognitive-behavioural interventions were found to be the most effective in terms of decreasing pain and distress (for further discussion see Cohen et al., Chapter 53; Liossi et al., Chapter 54; Logan et al., Chapter 50, this volume). There is promising but limited evidence for the efficacy of providing information and preparation (Uman et al., 2010).

Some studies have focused on developing techniques for preparing preschool and school-aged children for surgery. Educational programmes including a variety of coping models, sensory and procedural information, and structured medical play, have resulted in less situational anxiety and increased knowledge in children undergoing surgery in hospital settings (O'Conner-Von, 2000). A variety of interventions have been examined in terms of preparing children for surgery, such as individual and group preparation, videotapes, websites, and stress point preparation. Pre-surgery preparation strategies for children have been shown to be effective in reducing situational anxiety and increasing knowledge (O'Conner-Von, 2000). However, there is a paucity of research addressing educational needs of children and families of diverse cultural backgrounds, those undergoing emergency procedures and families of infants. Moreover, most research was conducted with children receiving inpatient care, yet the number of outpatient and day case procedures continues to rise placing increased responsibility on parents for pain assessment and management at home.

#### Parents' knowledge about pain

Regardless of culture or socioeconomic background, children find parents are their greatest source of support during a painful procedure (Jones et al., 2005). Unfortunately, little is known about parental perceptions and understanding of the information they receive about managing their child's pain (Oakes, 2011). Studies exploring parents' management of children's postoperative pain at home have found that even if they recognize their child is in pain, they often give inadequate doses of pain medication (Finley et al., 1996; Fortier et al., 2009). This is perhaps attributable to parental attitudes towards pain medications. Indeed, two studies conducted in the US found parents fear the negative side effects of analgesic drugs; consider analgesics to be addictive; and believe children should receive as little pain medication as possible (Zisk et al., 2007,

2010). Further, studies in the UK and Canada have found parents are satisfied with pain care, even if their child experiences moderate to severe pain during the postoperative period (Twycross and Collis, 2012; Twycross and Finley, 2013). Parents may not be aware of the harmful consequences of unrelieved pain. There is a need for health care professionals to educate parents about pain assessment and management.

Parents have indicated they would like more information about their child's pain management (Franck et al., 2005; Simons and Roberson, 2002; Simons et al., 2001). There is evidence of a wide variability in the amount of information, type of pain content, and clarity of pain information given to parents regarding their child's postoperative pain management (Tait et al., 2008). In Tait's study, parents ( $n = 187$ ) of children scheduled for surgery completed questionnaires about their perceptions, understanding, and satisfaction with the information they received regarding their child's postoperative pain management. Of note, parents whose child received patient-controlled analgesia were given significantly more information than those receiving nurse controlled analgesia ( $p < 0.025$ ). However, approximately one-third of parents had no understanding of the risks of pain management postoperatively. This reinforces the importance of providing pain management education to parents.

Several studies in North America have explored the effect of providing parents with an educational booklet about pain management following day surgery (Chambers et al., 1997), cardiac surgery (Huth et al., 2003), and in the emergency department (LeMay et al., 2010). There was some evidence parental knowledge increased following the educational intervention but limited improvements in pain management were found. However, in LeMay et al.'s study, the investigators found the use of an educational booklet was not effective in reducing pain and unpleasantness related to pain, nor did it improve pain beliefs held by parents ( $n = 195$ ). These investigators suggested having parents actively participate in their child's pain management would be more effective than a passive educational intervention such as a booklet. Similar results were noted in a study by Greenberg et al. (1999) using a videotape to increase parental ( $n = 100$ ) knowledge. Providing parents with information about pain is not sufficient; there is also a need to empower parents to take a more active role in advocating and caring for their child in pain. For a further discussion of pain and the family, see Birnie et al. (Chapter 12, this volume).

## **Strategies for educating children and parents about paediatric pain**

### **Strategies for educating children about pain**

Nurses have an obligation to educate patients about their health and to assess the patient and family's comprehension of the health care information (American Nurses Association, 2001, 2008; Association of Pediatric Hematology/Oncology Nurses, 2007; US Department of Health and Human Services, 1992). Nurses are usually the health care professionals responsible for educating children about pain (American Nurses Association, 2005; Kotzer et al., 1998), yet these guidelines and standards do not provide specific strategies for educating children about pain.

A variety of methods have been used to educate children about pain. Early educational strategies for children consisted of providing information through print materials, such as *My Book for Kids*

with *Cansur* by Jason Gaes (1987) and *The Berenstain Bears Go to The Doctor* (Berenstain, 1981). For younger children, puppets and dolls can be effective in explaining procedures (Child Life Council, 2007; Li et al., 2006). A variety of strategies have been used to educate children about pain, including print materials, therapeutic play, and cognitive-behavioural methods (Idvall et al., 2005). For younger children, puppets and dolls can be effective in explaining procedures, whereas older children and adolescents may prefer peer group or technology-based education (Child Life Council, 2007; Li et al., 2006). However, there is a lack of research addressing the importance of development in terms of designing educational interventions for children. In addition to cognitive development, the child's psychosocial development must be considered. For example, educational strategies for a younger child should involve parents, whereas involving peer mentors may be more effective for adolescents.

### **Web-based interventions**

Computers have changed the way we live, work, play, and learn (McGrath et al., 2010). Many children use technology in their educational and home settings using Web-based programmes is an obvious choice when designing strategies to educate children and adolescents about pain. Web-based technology has many advantages over the use of printed material. It is easy to individualize, update when new information is available, and can be interactive. Web-based education can provide information and guidance for patients without geographic or time restrictions (Brillhart, 2007). Technology has been used to educate children dealing with chronic pain (Palermo and Valenzuela, 2003), functional abdominal pain (Sato et al., 2009), cancer pain (O'Conner-Von, 2009), and arthritis pain (Stinson et al., 2012). However, more research is needed to evaluate the effectiveness of these educational interventions in terms of decreased pain intensity scores, increased knowledge of pain management strategies and improved functioning (i.e. school attendance and peer interaction). The relevant child population should be involved in the creation and critique of these programmes (O'Conner-Von, 2009).

The effectiveness of a Web-based programme designed to educate adolescents (aged 10–16 years) about tonsillectomy was tested by O'Conner-Von (2008). Children ( $n = 66$ ) were randomly assigned to a Web-based educational programme or to attend the standard educational programme at the hospital prior to the day of surgery. The Web-based programme contained the same educational content as the standard hospital-based educational programme. A script was created in conversational format with early and middle adolescents teaching each other about the surgical experience, pain assessment and management, and non-pharmacological ways to cope before and after surgery. To determine content accuracy and validity of the information provided in the programme, five adult experts who care for patients in this age group reviewed the script. Next, 40 healthy adolescents read the script to determine readability and age appropriateness. Lastly, two focus groups of six adolescents ( $n = 12$ ) who had undergone a tonsillectomy within the past year reviewed the Web-based programme and completed a questionnaire to rate the programme on ease of navigation, clarity of content, and age appropriateness. After completing the questionnaire, adolescents in the focus group sessions discussed their health care experience of having a tonsillectomy and their pain management during hospitalisation and

at home. Then participants discussed the programme in terms of what was most helpful, not helpful and how the programme could be improved.

Seventy per cent ( $n = 46/66$ ) of the patients had no prior surgical experience. On enrolment to the study, 70% of the participants reported fears related to surgery, the most frequent being fear of pain. Patients in the Web-based educational programme showed a statistically significant increase in knowledge acquisition ( $p = 0.0005$ ) compared to those assigned to the standard pre-surgery educational programme as well as increased satisfaction with the method of education ( $p = 0.004$ ). Although not statistically significant, pain intensity scores obtained 2-h and 24-h postoperatively were clinically significant; pain scores for patients who did not use the Web-based programme increased (mean score of 4.71 two hours after surgery, and a mean score of 6.09 twenty-four hours after surgery while at home). Patients using the Web-based programme reported advantages of this type of education such as the ability to view the programme as often as needed, when it was convenient, at their own pace, and in private.

### Strategies for educating parents about pain

An essential component of educating children about pain is to educate their parents. Just as children require age-appropriate explanations of pain, it is critical to assess parents' cognitive ability, understanding of pain, experience with pain, and readiness to learn, in order to provide appropriate education. The goals of educating parents about their child's pain are to improve knowledge and awareness of pain, to decrease misconceptions about pain, to provide pain relief, and to facilitate effective communication with the health care team (Curtiss, 2010; DiMaggio et al., 2010).

Over the past three decades, a variety of strategies to educate parents about pain have been used. Earliest materials consisted of providing information through print materials such as Children's Cancer Pain can be Relieved (Wisconsin Cancer Pain Initiative, 1989), Making Cancer Less Painful (McGrath et al., 1992) and Pain, Pain, Go Away: Helping Children with Pain (McGrath et al., 1994). A randomized trial (Chambers et al., 1997) evaluating the effects of educating parents ( $n = 82$ ) with the later booklet (a 15-page general guide to teach parents about assessment and management of pain) revealed that parents in the pain education group had fewer concerns about the use of paracetamol (acetaminophen) for their child undergoing day surgery and expressed more positive attitudes toward children's pain medications. However, there were no group differences in medication administration or pain assessment on the first 2 days after surgery. As a result of this study, the investigators concluded that simply providing print materials about pain is not enough to change parental behaviour, more targeted educational strategies are needed to improve parental pain assessment and management.

A recent exemplar of this type of targeted parental educational programme is the Pediatric PRO-SELF Pain Control Program which includes a comprehensive teaching booklet to increase parent's knowledge, pain management diary to track analgesic dosing, a timer to insure adherence with analgesic regimen, and interactive nurse coaching (Sutters et al., 2011). Further advances in technology provide pain education through real time telehealth (videoconferencing), social media (blogs), Web-based modules, and email or

text messaging with pain professionals. For example, the Arthritis Foundation website includes specific education on parenting a child with juvenile arthritis and interactive capabilities with medical experts to answer questions about treatment, easing pain, and coping strategies. Moreover, parents have noted that activities such as blogging to track their child's pain can be an invaluable coping tool (Kuttner, 2010). Technology provides new opportunities to educate parents about their child's pain. However, much research is needed in the methodological development of these strategies and to test their effectiveness. (See also Stinson and Jibb, Chapter 55, this volume.)

## Health care professionals' knowledge about paediatric pain

### Nurses' knowledge about paediatric pain

Over the past 15 years, seven studies have examined nurses' knowledge about paediatric pain (Table 63.1). The results of these studies suggest gaps remain in nurses' knowledge. These studies have not all used the same questionnaire, thus precluding precise comparisons. However, the results provide an indication of where gaps in knowledge are; there seem to be particular issues in relation to pain assessment, analgesic drugs, and non-pharmacological methods. The one study that took place in the developing world (Ekim et al., in press) suggests there are greater gaps in knowledge than in other countries. Further research is needed to explore this in other developing countries and to identify effective ways of providing required education.

### Other health care professionals' knowledge about paediatric pain

Little research has been carried out in relation to medical staffs' knowledge about paediatric pain. One study suggests paediatric residents (registrars) have gaps in knowledge similar to those identified with nurses (Saroyan et al., 2008). This pilot study tested the hypothesis that there are differences in residents' paediatric pain knowledge across different specialities (paediatrics ( $n = 26$ ), orthopaedics ( $n = 19$ ) and anaesthesiology ( $n = 15$ )). Paediatric residents had statistically significantly higher knowledge than those working in orthopaedics ( $p = 0.006$ ) and anaesthesiology ( $p < 0.001$ ). The paediatric residents on average answered 60% or fewer questions correctly. Questions relating to pain assessment for preverbal and cognitively impaired children were particularly poorly answered. There were also gaps in knowledge about the maximum daily dose of paracetamol (acetaminophen) and equianalgesic doses of different opioids.

Kolarik and colleagues, in one US hospital, explored paediatric residents' ( $n = 49$ ) perceptions about their educational needs in palliative care (Kolarik et al., 2006). Residents indicated they had little training, experience, or knowledge in most areas of paediatric palliative care and wanted more education regarding pain management. Similarly, a study amongst paediatric occupational therapists ( $n = 129$ ) found only a moderate awareness of issues relating to pain in children (Turnquist and Engel, 1994). Participants thought the education received prior to qualification was limited and their current knowledge was inadequate.

There is a paucity of research in this area but from the studies carried out we can surmise that knowledge deficits exist across all professional groups. Recent reviews of curricula content in the

**Table 63.1** Summary of studies examining nurses' knowledge

Ekim et al. 2012	Paediatric nurses (n=224) from five paediatric hospitals in Turkey Pediatric Nurses' Knowledge and Attitudes Regarding Pain Survey	<ul style="list-style-type: none"> <li>◆ Pharmacology and the use of opioid analgesia</li> <li>◆ Addiction</li> <li>◆ Accuracy of child's self-report of pain</li> </ul> Mean score: 38%

UK and Canada suggest limited input about pain within pre-qualification curricula (Briggs et al., 2011; Twycross and Roderique, 2011; Watt-Watson et al., 2009). This is despite the International Association for the Study of Pain (IASP) (2005) having published a Core Curriculum for Professional Education in Pain. The lack of pain content may impact on the quality of care provided to children and indicate a need for post-qualification training.

### Is knowledge used in practice?

For many years it was assumed that educating health care professionals about pain management would result in better care and clinical outcomes. More recently it has been acknowledged that while knowledge is necessary, it is not sufficient for better pain care. An additional consideration must, therefore, be whether health care professionals use their knowledge in practice (see also Yamada and Hutchinson, Chapter 61, this volume). Limited research has been carried out in this area but two studies have explored the relationship between paediatric nurses' theoretical knowledge and the quality of their pain management practices.

Vincent and Denyes (2004) examined the relationship between knowledge and nurses' (n = 67) analgesic administration practices.

They observed the care of children (n = 132), aged 3½ to 17 years, and found nurses with a better knowledge about pain were not more likely to administer pain medications. In the second study, the researcher shadowed nurses (n = 12) to collect data about their postoperative pain management practices (Twycross, 2007). Participants also completed a modified version of Salanter's paediatric pain knowledge questionnaire (Table 63.1). When questionnaire scores were compared to observational data no relationship between individual nurse's level of knowledge and how well they managed pain was found. Even when nurses had a good level of knowledge, this was not reflected in their pain management practices. This study had a small sample size but, along with the results of Vincent and Denyes' study, suggests nurses may not apply knowledge in practice consistently. Research relating to other health care professionals' use of pain knowledge in practice has not been carried out. Future research should explore whether similar findings occur across professional groups.

### Why isn't knowledge used in practice?

The Promoting Action on Research Implementation in Health Services (PARIHS) model was developed as a way of understanding

**Table 63.2** Elements of PARIHS model

Element	Sub-element
Evidence	Research
	Clinical experience
	Patient experience
	Local data/information
Context	Culture
	Leadership
	Evaluation
Facilitation	Low inappropriate facilitation
	High appropriate facilitation

Source: data from Rycroft-Malone, J, Promoting Action of Research Implementation in Health Services (PARIHS), in Rycroft-Malone, J and Bucknall, T (eds.), *Models and Frameworks for Implementing Evidence-Based Practice: Linking Evidence to Action*, Wiley-Blackwell, Oxford, UK, pp. 109–136, Copyright © 2010.

the complexity of implementing evidence (and knowledge) into practice (Rycroft-Malone, 2010). The model provides a structure to support behaviour change and consists of three elements (Table 63.2), focusing on the interaction of the quality of the evidence with the context, and methods of facilitating knowledge translation. All three elements impact on health care professionals' readiness to change their pain practices thus providing an explanation for why education alone is not enough.

Gaps in knowledge about the pharmacology of analgesic drugs and the anatomy and physiology of pain may mean the rationale for implementing pain-relieving interventions is not understood. If health care professionals lack knowledge about pain assessment they may lack confidence, or be unable, to assess children's pain. Similarly if knowledge deficits exist in relation to non-pharmacological methods of pain-relief health care professionals may not feel confident using these strategies. If the PARIHS model is applied, gaps in knowledge may mean health care professionals do not have access to the evidence to use in practice.

Beliefs and attitudes are related to individual's knowledge and clinical experience and thus link to the PARIHS model. Nurses appear to believe some pain is to be expected (and accepted) during hospitalization (Hamers et al., 1994; Woodgate and Kristjanson, 1996). Further, nurses may see pain management as synonymous with administering analgesic drugs (Twycross, 2004; Twycross et al., 2013). Nurses may not attribute as much priority to pain management as they do to other aspects of their role (Twycross, 1999; Vincent, 2005). Although it should be noted the importance nurses attribute to pain management tasks does not necessarily reflect the likelihood of the task being undertaken in practice (Twycross, 2008).

Context is one of the elements of the PARIHS model. Over the past decade there has been a growing awareness that a ward/unit has a set of informal rules that determine how pain is managed. This was demonstrated by the results of Lauzon-Clabo's (2008) ethnographic study on two (adult) wards in one hospital in the US. Participants described a clear but different pattern of pain assessment on each ward. The social context of the ward appeared to influence practices. Further, in one Canadian study, paediatric nurses described the unit's pain management culture as giving pain medications regularly even if they are prescribed

prn; this appeared to be the factor that impacted most on practice (Twycross et al., 2013). Context clearly has a place in ensuring knowledge is used in practice. Indeed, it has been postulated that pain management practices remain poor because contextual factors are not taken into account (Bucknall et al., 2001; Craig, 2009). Future research should explore strategies that facilitate sustainable changes in unit culture.

The PARIHS model describes facilitators as having a key role in changing practice (Harvey et al., 2002). Indeed, a systematic review concluded that the use of local opinion leaders was an effective way of promoting evidence-based practice (Flodgren et al., 2011). As part of an action research project, Williams et al. (2010) evaluated the impact of pain resource nurses (PRNs; link nurses) acting as local opinion leaders (n = 30) in two Australian hospitals. Results demonstrated that 11 months after the introduction of PRNs:

- ♦ More patients had a pain score recorded on the daily observational chart ( $\chi^2 = 6.038$ ,  $p = 0.014$ ) and in the nursing care plan ( $\chi^2 = 5.11$ ,  $p = 0.024$ ).
- ♦ An increase in the number of patients with a pain score documented each nursing shift (morning shift:  $\chi^2 = 35.146$ ,  $p < 0.001$ ; afternoon shift:  $\chi^2 = 11.717$ ,  $p < 0.001$ ; night shift:  $\chi^2 = 10.700$ ,  $p < 0.001$ ).
- ♦ No differences were noted in other areas.

PRNs may be a useful strategy for improving documentation practices. Further evaluation is needed to explore the impact on patient outcomes.

Some of the reasons knowledge is not used in practice have been explored using the PARIHS model. As well as helping us understand why knowledge is not always used in practice it also helps to identify which interventions may help to address this.

## Strategies for educating health care professionals about paediatric pain

### Educational strategies

A literature review carried out in 2002 concluded that not all educational interventions designed to improve health care professionals' knowledge about pain actually did so (Twycross, 2002). Successful programmes used a variety of teaching methods (interactive and didactic) and encouraged students to reflect on practice. Francke et al. (1995) had some success using confluent education methods that emphasize the importance of integrating left-brain knowledge with right brain creativity. This is similar to a stance adopted by Murinson et al. (2011). These teaching methods help ensure the integration of theory and practice, and acknowledge learner's feelings and experiences (Francke and Erkens, 1994). Examples of these teaching methods can be seen in Box 63.1.

Using a variety of teaching strategies to enhance learning is supported by the results of a systematic review, exploring the effectiveness of continuing medical education in changing practice and health outcomes (Foresetlund et al., 2009). Educational meetings alone are unlikely to change complex behaviours. Two factors were found to increase the likelihood of behaviour change and improved patient outcomes: using a mixture of interactive and didactic teaching methods, and focusing on outcomes perceived as serious. However, the effect is likely to be small

**Box 63.1** Examples of confluent education methods

- ◆ Using students' clinical experiences within group discussions
- ◆ Role play
- ◆ Clinical simulations
- ◆ Gaming
- ◆ Case studies
- ◆ Reflection on what individuals have learnt from the sessions
- ◆ Reflection on how this learning will be applied in practice
- ◆ Students sharing how will apply learning in practice (with the group).

**Educational outreach visits**

Educational outreach visits (EOVs) involve people visiting clinicians where they practise and providing them with information to change how they practise (Soumerai and Avorn, 1990). EOVs can take many forms. Some examples of the strategies used are provided in Box 63.2. A systematic review of 69 studies examined the effectiveness of EOVs on changing practices and health care outcomes (O'Brien et al., 2008). EOVs alone, or combined with other interventions, have a relatively consistent but small impact on prescribing practice. Their effect in other areas varied from small to modest improvements.

The impact of EOVs on pain management practices in primary care has been explored in one study (Schechter et al., 2010). A 1 h teaching session on pain reduction strategies during childhood immunizations was provided to staff in 13 practices in one state in the US. At 1 month parents were: more likely to report receiving information ( $p = 0.04$ ); using strategies to reduce pain ( $p < 0.01$ ); learning something new ( $p < 0.01$ ); using a Shotblocker® ( $p < 0.01$ ); and higher levels of satisfaction ( $p = 0.015$ ). Rates all remained higher at 6 months ( $p < 0.01$ ) except for satisfaction. Clinician surveys at 6 months revealed significant increases in the use of longer needles (infants:  $p = 0.34$ ; toddlers:  $p < 0.001$ ; adolescents:  $p = 0.002$ ), sucrose ( $p = 0.003$ ), pinwheels ( $p < 0.001$ ), focused breathing ( $p = 0.021$ ), and Shotblockers® ( $p < 0.001$ ). There was no statistical difference in the use of topical anaesthetics. EOVs may be a useful strategy for changing pain management practices but further research is needed.

**Individual feedback**

Audit and feedback can be a useful method for changing practices within clinical areas but the effects are variable and are particularly effective where there is low compliance with a given standard (Jamtvedt et al., 2006). The effect of individual feedback

**Box 63.2** Examples of EOV activities

- ◆ Feedback about performance
- ◆ Feedback on previously identified obstacles to change
- ◆ Mini-education sessions
- ◆ Roving education rounds
- ◆ Teaching moments.

on paediatric pain management practices has been explored in a clustered randomized trial in six Canadian paediatric hospitals (Johnston et al., 2007). Coaching with individual audit feedback from a chart review was provided every 2 weeks, for 6 months, by an opinion leader. Some changes were found between the experimental and control groups although there were inconsistencies across sites. For example:

- ◆ Documented pain assessments increased in the coaching group (from 15% to 58%,  $\chi^2 = 138.34$ ,  $p < 0.0001$ ) and decreased in the control group (from 24% to 9%,  $\chi^2 = 34.86$ ,  $p < 0.001$ ).
- ◆ The use of non-pharmacological interventions increased in the coaching group (from 5% to 16%,  $\chi^2 = 28.48$ ,  $p < 0.0001$ ) and decreased in the control group (from 1.5% to 0.3%,  $\chi^2 = 2.23$ ,  $p =$  not significant).
- ◆ Nurses' knowledge increased in the coaching group but decreased in the control group ( $F(1, 791) = 106.3$ ,  $p < 0.0001$ ).

Coaching has also been used successfully with nurses caring for (adult) patients undergoing an arthroscopy (Duncan and Pozehl, 2001). However, providing individual feedback is resource intensive; an economic evaluation needs undertaking before implementing this strategy more widely.

**Web-based interventions**

Web-based educational courses are becoming more common partly because in today's health service there is a need to ensure health care professionals receive education in as cost-effective way as possible. The English Department of Health advocate the use of e-learning as one way of addressing this issue (Department of Health, 2008). One paediatric pain e-learning product was launched in February 2012 and is made up of six units that can be purchased together or individually covering:

- ◆ Pharmacology of analgesic drugs
- ◆ Anatomy and physiology of pain
- ◆ Pain assessment
- ◆ Non-pharmacological methods of pain-relief
- ◆ Managing acute pain
- ◆ Managing procedure-related pain.

The course is aimed at registered health care professionals. Further information can be found at: [http://www.healthcare.ac.uk/cppd/short-courses-postgraduate/managing-pain-in-children-\(elearning\)/>](http://www.healthcare.ac.uk/cppd/short-courses-postgraduate/managing-pain-in-children-(elearning)/>).

Web-based courses need evaluating to ascertain their effectiveness in increasing knowledge and changing practice, as well as exploring how their impact compares to courses taught face-to-face. One randomized controlled trial has compared the effectiveness of Web-based training about the use of opioid therapy for chronic pain to being given a copy of current clinical guidelines for internal medicine residents (Sullivan et al., 2010). The Web-based group had a greater increase in knowledge ( $p < 0.00001$ ) and higher self-ratings of their competence in overall management (Wald  $\chi^2 = 5.17$ ,  $df = 1$ ,  $p = 0.02$ ) and in prescribing opioids (Wald  $\chi^2 = 5.17$ ,  $df = 1$ ,  $p = 0.02$ ). However, the Web-based training also covered shared decision-making (patient and doctor) and communication skills; it may have been this difference rather than the content relating to the use of opioids that was effective. Another study evaluated the effect

of a Web-based palliative care module for medical residents in one US hospital (Dy et al., 2008). Knowledge about palliative care did not increase simply by completing the 4-year residency programme but undertaking the Web-based course resulted in a larger increase in knowledge.

## Conclusion

Children and parents require education about pain and pain management. To date there is little research exploring the best ways to provide this education other than in relation to preparing children for surgery or painful procedures. When developing educational materials for children cognitive and psychosocial factors need taking into account. There is a need to create and test educational resources for children. Resources are needed for parents that increase knowledge as well as supporting them to advocate for their child. Technology provides new opportunities in this context.

Gaps remain in health care professionals' knowledge about pain that are greater in the developing world. Further research is needed to explore this across all professional groups. For practices to change education needs to be provided alongside other strategies promoting the use of knowledge in practice; education alone is not enough. The PARIHS model has been used to provide an explanation for why knowledge is not used in practice. This needs testing further; organizational culture and the role of facilitation need particular attention. Educational interventions should include a mixture of interactive and didactic teaching. Strategies that help link education with practice should also be encouraged such as reflection, clinical simulations, and the use of case studies. Web-based materials are available but their effectiveness needs evaluating.

## CHAPTER 64

# The ethics of pain control in infants and children

Gary A. Walco and Maureen C. Kelley

### Introduction

A common theme throughout writings in paediatric medicine is that ‘children are not little adults’, often referring to physiological and psychological differences related to maturation and development that must be taken into account in providing care. Similarly, in considering ethical challenges related to pain, it is important not to simply extrapolate from our ethical approach to pain management for adults who typically can describe their experience of pain, are fully responsible for themselves, and can represent their own interests in making treatment decisions. Unlike adults, younger children and certainly infants cannot speak for themselves and require parents and clinicians to assess their pain, determine what is in their best interest, and advocate for their well-being. However, in paediatrics, these assessments occur in the context of a child’s evolving developmental capacities: as older children and adolescents mature, they begin to understand and participate more in decisions affecting their health, to report symptoms, and to communicate their wishes. In addition, as with other areas of clinical ethics, determination of the best ethical practice must be considered against the backdrop of evolving data and evidence. Recent advances in the science of pain assessment can help inform the balance of competing ethical values related to pain in infants and children.

In this chapter we will offer a way of framing the ethical balance of competing considerations in pain treatment in infants and children, distinguishing between analyses of harms and benefits, from other more pragmatic, contextual, and cultural considerations. We begin with the ethical foundations behind good pain management for any patient, and especially children: the ethical duty to prevent harm by alleviating pain or suffering, and the importance of assuring equal access to pain treatment. Historically, the driving ethical concern in paediatric pain has been the pervasive undertreatment of pain in children. In the second and main section of the chapter, we offer a detailed analysis of the practical ethical challenges involved in weighing the harms and benefits of pain relief against untreated or undertreated pain. In the third section, we will discuss the more specific concerns of socioeconomic and cultural determinants to paediatric pain treatment. Finally, in the last section, we will address concerns in conducting research on pain

interventions in infants and children, as clearly many of the modal methodologies traditionally used for clinical trials in adults (e.g. placebo control designs) pose unjustifiable risk to younger individuals. We will also discuss the importance of considering local context as it impacts standards of care to guide ethical paediatric pain research.

### Ethical foundations of clinical pain control in paediatrics

The starting point in thinking about the ethics of pain control in paediatrics is relatively uncontroversial at first glance. Few would disagree that alleviating suffering is fundamentally a good thing, especially among the youngest and most vulnerable human beings, and should thus be pursued universally. Failure to address pain in any patient would constitute a straightforward violation of the Hippocratic harm principle: ‘First, do no harm’ (Adams, 1891). Further, failure to address pain, when we have the means to do so, violates an important and basic human right to dignity and prevention of suffering (James, 1993). While the harm principle is an effective argument against undertreatment of pain, the rights argument lends a more powerful universal appeal to the case for expanding access to pain treatment to all children, regardless of background, socioeconomic status, or geographical location (Southall et al., 2000). Such a perspective shapes the position of the World Health Organization on pain in children (World Health Organization, 1998), and the recent International Association for the Study of Pain, the Declaration of Montreal (Cousins and Lynch, 2011), which states:

Recognizing the intrinsic dignity of all persons and that withholding of pain treatment is profoundly wrong, leading to unnecessary suffering which is harmful; we declare that the following human rights must be recognized throughout the world:

*Article 1.* The right of all people to have access to pain management without discrimination.

*Article 2.* The right of people in pain to acknowledgment of their pain and to be informed about how it can be assessed and managed.

*Article 3.* The right of all people with pain to have access to appropriate assessment and treatment of the pain by adequately trained health care professionals.

Because pain is very common in hospitalized children, the International Association for the Study of Pain, Special Interest Group on Pain in Childhood supported the Bellagio Declaration (ChildKind International, 2010), calling for all health care facilities to commit to the developmentally appropriate prevention, assessment, and management of pain in children and adolescents aged 0 to 18 years. Lack of knowledge and subjective biases often have influenced decision-making about pain treatment in children, leaving the deleterious effects of untreated pain minimized or ignored. Such deleterious outcomes violate the principle of do no harm and a comprehensive and balanced analysis, relying on data rather than personal bias or speculation, is required.

For addressing pain in older children and adolescents, developmental appropriateness in clinical assessment and interventions also tracks to the involvement of the more mature paediatric patient in pain management decisions. The growing literature in child development over the past two decades has helped shape a much more nuanced approach to ethical decision-making with adolescent patients. The now standard ethical model calls for the increasing respect for the developing autonomy of teens and young adults as they develop the capacities to understand medical information, appreciate the implications of various health decisions, and develop the ability to weigh the risks and benefits of immediate and long-term consequences (American Academy of Pediatrics Committee on Bioethics, 1995). These decisions are ideally made with parental permission and support, not in isolation, but as paediatric patients are increasingly able to participate in important health decisions, they should be encouraged to do so, and their questions, concerns, and decisions should be increasingly respected (Ross, 1998). In the context of pain, this requires listening carefully and principally to the voice of the patient, since even the most well-meaning parents may err in interpreting the symptoms of suffering or pain in their own children. Beyond the very important principle of respecting the adolescent patient's emerging voice and autonomy, so much of good pain management depends on quality communication with the patient. Actively involving more mature patients becomes particularly important in addressing recurrent or chronic pain and in palliative settings, where ongoing relationships with patients are so important to providing the best care.

## Balancing harm and benefit of paediatric pain control in clinical practice

Withholding pain treatment without further justification constitutes a violation of the harm principle in medicine, and may, as well, constitute unjust suffering and violation of the basic human right to dignity and non-discrimination in health treatment. However, as is often the case in practical clinical ethics, the apparent 'no brainer' of alleviating pain and suffering in an unqualified manner becomes a bit less straightforward in clinical practice (Lantos and Meadow, 2007). While the ethical foundation driving improved pain treatment and control in children provides strong impetus for addressing undertreatment or unequal access to treatment, we need a more nuanced approach to guide actual clinical decisions at the bedside. The balance of harm and benefit in alleviating pain in infants and children needs to be evidence based and requires appreciation of context. As the evidence evolves, preventing or minimizing present and long-term harm in children can become a more challenging balancing act. The expression and meaning of pain are subject

to cultural influences; it is a significantly subjective experience. Because we do not have undisputed data to guide us on many of the decisions we make, individuals' perspectives come into play.

Walco et al. (1994) argued that because pain and related suffering seem harmful to patients, and because caregivers are categorically committed to preventing harm in their patients, not using all available means of relieving pain must be justified. Both sides of this balance, however, have shifted a great deal over time. As outlined by Olmstead et al. (2010), our thinking on this topic has evolved. Until about four decades ago, the general lore was that young children, in particular, did not experience pain and certainly had no lasting memory of it if they did. Thus, the harm of untreated pain was not recognized. In the late 1970s and onward, there was increasing recognition that pain was undertreated in children compared to adults and that even very young premature infants have nociceptive systems in place and thus have capacity for pain perception. The work of developmental physiologists provided even greater insights and by the turn of the century, there were ample data to show that untreated or undertreated pain in young children was associated with lasting deleterious effects (Fitzgerald, 2005) (see Grunau, Chapter 4, this volume).

Three potential justifications have been proposed for not adequately treating pain in children, namely revisionist, comparative, and pragmatic justifications (Walco et al., 1994).

First, because pain is fundamentally a private, subjective experience, it is difficult to assess with validity, especially in the youngest patients who do not express themselves verbally. A *revisionist* justification focused principally on aspects of pain assessment in the young and involves a tendency for care providers to 'overrule' or 'revise' evidence of pain based on a number of preconceived notions, such as believing there is a 'correct' amount of pain associated with a given degree of tissue damage or pathophysiological condition, as well as attributions to other more benign factors (the infant is cold or hungry as opposed to in pain). In the last two decades, the field has come a long way in demonstrating reliable, valid, and clinically sensitive means of assessing pain in children of all ages (see Lee and Stevens, Chapter 35; von Baeyer, Chapter 36, this volume). Because many of the existing measures are based on physiological indicators that may be non-specific to pain, as well as observed behavioural indicators that are dependent on the expertise and knowledge of the observer, there is still risk of care providers revising or minimizing the significance of pain responses. Developing more objective indicators with enhanced reliability and validity would be most helpful (see Lee and Stevens, Chapter 35, this volume). However, to minimize or discount available data because we lack ideal assessment methods does not justify undertreating pain in the interim.

In revising children's pain complaints, care providers make implicit judgements about the validity of those responses. Such judgement and invalidation is most obvious in the use of placebos to treat pain. The clinical use of placebos to treat pain may fulfil patient and family expectations to receive *some medication* to treat the condition as well as a clinician's aim to promote a desired clinical outcome using 'inert' substances (Miller and Colloca, 2009). Consider an instance in which a child or adolescent continues to complain of pain despite being administered what is deemed by the practitioner to be sufficient quantities of analgesic medication. Especially when observed pain behaviour is inconsistent or does not match up with verbal reports, there is a tendency to attribute

the pain to other than nociception, which may be 'proven' by the patient experiencing pain relief with a placebo.

Using placebos in this setting is problematic for a number of reasons. First, there is a great deal of literature to show that placebo effects operate across circumstances, including when there is little or no doubt of the pathophysiological basis of the pain (Foddy, 2009). Thus, the presumed purpose of using placebo, to determine if the pain is 'real' cannot be achieved. Second, once the patient becomes aware of the clinician's intentional deception, trust is lost not only in that provider, but in providers throughout the medical system in general (Cahana and Romagnoli, 2007; Foddy, 2009). Third, and related, if the clinician uses placebo to acquiesce to the desires of parents or family members, the threat of trust being violated extends beyond the immediate clinician-patient relationship as generalization to healthcare providers in general is possible. As a result, there is consensus, including a strong statement from the American Medical Association (Bostick et al., 2008), that the clinical use of placebos without informed consent is categorically unethical (Cahana and Romagnoli, 2007; Foddy, 2009).

A *comparative* justification focuses on weighing the benefits and risks of unrelieved pain against those of pain relief. In some circumstances, a responsible conclusion may be that the harm of unrelieved pain is less severe than the harm of pain relief. Many of the traditional concerns have focused on fears of addiction and dangerous side effects of analgesic medications, neither of which may be taken lightly. With regard to the former, certainly there is concern for misuse and addiction of opioids among children and adolescents, especially those prescribed to others and subsequently scavenged by adolescents (Bailey et al., 2009). There is little to show, however, that there is risk of addiction when these medications are appropriately prescribed and administered in paediatrics settings (Yaster et al., 2003). Thus, if one is careful about prescribing appropriate dosages and, in particular, the amount of medication prescribed in ambulatory settings, withholding opioids for pain management due to fear of addiction is not justified—this is true for all ages.

The second concern, deleterious effects of analgesic medications, requires careful cost-benefit analysis when weighing efficacy against adverse events. A common concern of opioids focuses on significant sedation and respiratory depression and, more recently, questions about long-term deleterious effects of opioid administration on cognitive development in the young have arisen.

A recent prospective study reported on the incidence, nature, and severity of serious clinical incidents (SCIs) associated with continuous opioid infusion, patient-controlled analgesia, and nurse-controlled analgesia in neonates, infants, and children under the care of paediatric acute pain teams in the UK and Eire (Morton and Errera, 2010). Predefined SCIs fell into three grades: (1) death/permanent harm; (2) harm but full recovery, technique stopped or changed, intervention required; and (3) potential harm but no actual harm. With a denominator of 10 726 opioid infusions, there were one Grade 1 SCI (cardiac arrest associated with aspiration pneumonitis and an underlying neurological condition), 28 Grade 2 SCIs, half of which were respiratory depression, and 17 Grade 3 SCIs (all of these last category occurred in a single centre related to programming or prescribing errors). It is noteworthy that of the 14 cases of respiratory depression, half of the children were less than 1 year of age. The authors emphasized the need for heightened monitoring for children posing increased risk factors, including

very young age as well as neurodevelopmental, respiratory, or cardiac comorbidities.

In children over the age of 2 years, there is consensus that the data on the safety and efficacy of opioid medications parallel findings in adults (Berde et al., 2012). However, based on developmental factors, the pharmacokinetics and pharmacodynamics of opioids are more variable in younger children. Clinically, this means that, especially in preterm and younger infants, the risk of deleterious effects, such as respiratory depression, may be greater (Simons and Anand, 2006). Thus, increased scrutiny in prescribing and administering opioid medications is needed, with special attention to aspects of the patient's status that may place them at increased risk for such complications. However, once again, these concerns should not automatically deter the use of methods to alleviate pain, recognizing that such adverse outcomes may be mitigated by proper monitoring.

A review of the literature conducted under the auspices of the American Society for Pain Management Nursing showed that there are no universally accepted guidelines to direct effective and safe assessment and monitoring practices for patients receiving opioid analgesia (Jarzyna et al., 2011). Furthermore, there have been very limited carefully controlled studies to show the actual benefits of specific monitoring methods, including pulse oximetry and capnography, in hospitalized patients receiving opioids for pain. With this as background, a position paper was generated highlighting the need to evaluate the individual patient for risk factors, including age, anatomic anomalies, physical characteristics, primary and comorbid medical conditions, psychological states, and functional status; of note risk associated with age was focused only at the upper end of the spectrum (>65 years). Based on these risk factors and the nature of the intervention, monitoring to detect difficulties early on, before serious adverse events, is deemed essential. With these safeguards, patients are not denied access to pain relieving strategies but risks of respiratory depression may be minimized. In addition, in the unfortunate circumstance when respiratory depression is of clinical significance, effective reversal agents may be used (American Academy of Pediatrics Committee on Drugs 1990). It should be noted that the guidelines espoused by Jarzyna et al. do not focus at all on paediatric populations and our review yielded no similar documents addressing the needs of children. Certainly patient safety may be enhanced with evidence-based monitoring practices for children, thereby better addressing concerns about untoward side effects of opioids used to reduce pain.

There is some question as to whether prolonged use of opioids, especially in very young infants, may have deleterious long-term effects. Specifically, opioids have often been used on an ongoing basis in an attempt to maintain the comfort of neonates who were receiving mechanical ventilation. A 5-year follow-up study indicated, however, that there may be some significant effects on intellectual functioning associated with this practice (de Graaf et al., 2011). While these data certainly serve as an alert, it is difficult to attribute deleterious outcomes specifically to opioids as there is an array of developmental, medical, and environmental factors that may impact the relatively unstable physiological systems of premature neonates (Grunau et al., 2006; see also Grunau, Chapter 4, this volume). Thus, a simple concept of 'the more the better' in utilizing agents to reduce pain and distress may need to be tempered as more data emerge (Lantos and Meadow, 2007; Mancuso and Burns, 2009).

The *pragmatic* justification focuses on the potential benefits of pain persisting. In other words, while it is acknowledged that unrelieved pain is bad, such pain may be deemed necessary to achieve a greater goal. Two general areas may be cited here, the value of pain to provide diagnostic information and the utility of pain to help build character. In the former, pain may be seen as useful to monitor an illness (cf. Bromberg and Goldman, 2007) or to indicate the ineffectiveness or limits of treatment, such as discomfort during rehabilitation after orthopaedic surgery. Eliminating or masking such pain could actually harm the patient and therefore one must weigh the benefit of immediate relief against that of long-term recovery. In such circumstances, the clinician is deemed to be operating in the patient's best interest by maintaining a degree of pain or discomfort. To assure that is the case, three specific tests should be applied. First, is the pain useful—is it the means to achieving an important goal? Second, is the pain necessary or are there other, less hurtful means of achieving that goal? Third, is the pain at the lowest possible level? Because it is not acceptable to allow children to suffer if there is any other means of achieving outcome data, if there is a therapeutic benefit from a child's pain, one must be exquisitely economical with it.

A second potential pragmatic justification derives from moral views held by some that champion traits such as courage, self-discipline, independence, and self-sacrifice. Such cultural or family views about pain may also track beliefs about gender differences: for example, that a young girl should learn to tolerate severe menstrual pain, or that a boy ought to 'tough it out' through a sports injury. Although in principle encouraging such virtues as bravery and stoicism may be ethically defensible, imposing the burden of character development on a child already encumbered by distress, sickness, or suffering reflects a lack of compassion and is ethically questionable, at best. When the total eradication of pain is not possible (as in the case of chronic pain associated with chronic illness), strengthening the child's capacity to cope with the pain is beneficial and may be justifiable. However, to intentionally allow a child to suffer in the hope of influencing character development disregards the child and the real and present need for pain relief. The scope of parental discretion, including refusals of pain treatment for reasons of character building, should be constrained by appeals to the harm principle (Diekema, 2004).

A fairly pervasive example of this phenomenon may be seen in the failure of broad-scale efforts to treat needle pain. Often statements reflecting the view that pain is a part of life and children need to cope with it serve as justification for failing to treat pain associated with needles (Taddio et al., 2009). The unfortunate outcome is that immunization rates are lowered by individuals who avoid needles and an estimated 10% of adults avoid contact with medical institutions, even when indicated, due to fear of needles (Hamilton, 1995).

Nearly 20 years ago, Walco et al. (1994, p. 543) concluded, 'All health professionals should provide care that reflects the technological growth of the field. The assessment and treatment of pain in children are important parts of paediatric practice, and failure to provide adequate control of pain amounts to substandard and unethical medical practice'. Unfortunately recent data on required and optional coursework indicate that medical school education in North America falls well short of the mark in preparing practitioners to make these informed decisions (Mezei and Murinson, 2011).

In many ways, as the knowledge base for the assessment and management of pain grows and medical education fails to keep pace, problematic outcomes appear even more amplified. A recent report from the Institute of Medicine (2011) focuses specifically on how lack of education and the overgeneralization of management principles related to acute pain have contributed to epidemic concerns about chronic pain. Certainly children are not immune from these same issues (McGrath and Ruskin 2007) and the problem is compounded by data indicating that untreated chronic pain in children and adolescents predisposes individuals to ongoing chronic pain problems well into adulthood (Dengler-Crish et al., 2011; Walker et al., 2010).

Armed with data on the poor treatment of pain in infants and children, there have been a number of initiatives advocating for improvement. Included here is a policy statement jointly issued by the American Academy of Pediatrics and the American Pain Society (American Academy of Pediatrics Committee on Psychosocial Aspects of Child and Family Health, American Pain Society Task Force on Pain in Infants, Children, and Adolescents 2001), a position statement of the International Association for the Study of Pain (IASP SIG on Pain in Childhood 2005), and a monograph by the World Health Organization (1998), all of which highlight the undertreatment of pain in infants and children and the need for improvements in the assessment and treatment of pain and suffering.

## Recognizing socioeconomic and cultural determinants to pain control

As paediatric pain medicine has improved drastically in developed countries and for families with good access to health care, the next frontier in improving access to better paediatric pain treatment is to address the inequalities of paediatric pain management for underserved patients and families. If untreated pain is an unjust suffering, on either the rights argument or the basic requirement of the harm principle, we have reason to address disparities in access to pain control in children between high-resource and low-resource communities. Included among such communities are not only low-income countries, but also low-income neighbourhoods and regions in middle-to-high-income countries. Just as with adults, children the world over experience acute and chronic pain, and yet we still lack robust epidemiological data on childhood and adolescent pain prevalence (Berde et al., 2012; King et al., 2011). Accurately mapping the global burden of any disease is the first step in recognizing suffering, and a necessary step toward addressing a need in sometimes marginalized populations.

As our understanding of the global burden of paediatric chronic and acute pain prevalence and causes improves, we can more effectively target the scale-up of pain treatment regimens in underserved areas. The most pressing immediate need is for pain medicines and supplies, and improved clinical training for pain diagnosis and treatment among medical care providers. Implementation of pain programs require evidence-based advocacy from professional organizations, and an appeal to the arguments from ethics and social justice presented above.

Those advocating for better access to pain control in resource-poor communities also face a perception that there are more dire needs to be met first—for example, malaria, childhood vaccination, clean water, or nutrition. Because a child's pain left untreated is an

unjust suffering, except in the cases where the pain treatment would cause more harm than the pain itself, pain treatment cannot be viewed as a luxury. It should be viewed as equally critical, alongside the provision of preventive care, such as vaccinations, and the treatment of acute infections and other endemic diseases that disproportionately affect children living in poverty. For health professionals serving children and families in poor communities, greater effort may be required to advocate for coverage of good pain management and of palliative care when resources are not readily available.

As we expand efforts to improve access to effective pain management for all families across socioeconomic and political borders, we will also encounter a wider array of cultural beliefs about pain. Pain is a subjective experience imbued with social and cultural meaning, and this known variation in the experiences of pain has three significant ethical implications for practice in diverse patient populations (Craig and Pillai Riddell, 2003).

First, social and cultural factors may impact whether and to what degree parents pursue or have adequate access to information and resources for addressing their child's pain. Given that there is variation in parents' acceptance of exposures to pain, injury, or risk in children (Goodman and McGrath, 1991), children from some communities may be at greater risk for injury and pain, and less likely to have access to treatment. In this case, undertreatment of paediatric pain may be consonant with other socioeconomic determinants of health care access for children from marginalized groups or communities and could be embraced as part of a more general effort to address health disparities in child health.

Second, specific cultural beliefs may discourage the expression or reporting of pain as a weakness, making it more difficult to assess pain in a child patient. For example, one study of Somali families reported a belief that adults and children, especially men and boys, are expected to be stoic when in pain and not openly express pain (Finnstrom and Soderhamn, 2006). For providers treating children from culturally diverse communities, approaching families with cultural humility—asking questions to help understand beliefs about a child's pain—can help inform a respectful approach to these patients, while also being alert to the potential underreporting of pain. In approaches to treating chronic pain and end of life care, it is also important to distinguish cultural beliefs and practices of a particular family from lack of knowledge about the nature of pain in a child or unfamiliarity with available treatments (Zalon et al., 2008). In such circumstances providers have an opportunity to educate parents about the biological and sensory nature of pain in children, ultimately to help them understand when pain treatment is necessary for alleviating a child's physical suffering.

Third, perceptions or beliefs among providers and other systemic factors may lead to disparities in the treatment of pain for some minority families and communities. For example, a review of pain studies in adult patients in the United States demonstrated that blacks and Hispanics are more likely to be undertreated for pain than white patients (Bonham 2001). More data are needed to understand the exact causes of such patterns of undertreatment, but a first step is to be alert to patterns of discrimination and to highlight the importance of correcting such disparities in pain management training and practice by emphasizing the universally experienced phenomena of pain across ethnic populations (Edwards et al., 2005).

In those cases where a parent's cultural beliefs discount a child's pain—for example, 'in our culture it is important for a boy to be

strong; my son does not need morphine'—a provider's fundamental ethical duty is to minimize harm and suffering for the patient, but this can be managed with cultural sensitivity. As argued earlier in considering pragmatic appeals to non-treatment of pain, the duty to prevent harm and the rights argument ought to outweigh any cultural appeal to allowing pain in children. Where adults may be free to martyr themselves or choose to undergo suffering and pain for a greater good or for deeply held spiritual or cultural beliefs, they are not free to martyr their children (*Prince v Massachusetts*, 1944). In practice, there are more sensitive and effective ways to navigate cultural beliefs in a family. Understanding cultural perceptions of pain can help shape care providers' conversations with families about pain management; introducing current models of pain mechanisms and processing may counter cultural beliefs that mitigate adequate pain treatment. In the end, awareness of cultural underpinnings for undertreatment of pain can help shape clinical strategies but does not alter the basic moral obligation to treat a child or infant's pain. (Please see Clemente, Chapter 11, this volume.)

## Ethical considerations in paediatric pain research

As already discussed, optimal clinical decision-making is based on evidence. The more data we have on the safety and effectiveness of available treatments for the population to which they will be administered, the better. If, for example, we wish to understand the safety and efficacy parameters of using a specific analgesic medication for pain relief in premature neonates, ideally we would have data from pharmacokinetic and pharmacodynamic studies, as well as from efficacy trials conducted in that population at our disposal (Anand et al., 2006). However, there are some significant ethical and pragmatic challenges to be addressed in order to do so.

The US government enacted a series of laws seeking to improve knowledge of the safety and efficacy of specific drug preparations as applied in paediatric population. These included the Food and Drug Administration Modernization Act (FDAMA) of 1997, the Best Pharmaceuticals for Children Act (BPCA) in 2002, and the Pediatric Research Equity Act (PREA) in 2003 (Sachs et al. 2008). As a function of these initiatives, as of 4 January, 2012, there have been 426 labelling changes, including 388 trials involving children. Although these results are certainly encouraging there have been very few labelling changes for medications specifically indicated for pain.

Thus, in our current state, for children under 6 months of age, there are no medications labelled for pain relief. For children between 6 and 24 months, only ibuprofen has been approved for analgesia, and for those older than 2 years, the list expands to include oral acetaminophen, aspirin, meperidine, hydrocodone, tolmetin, the combination product of acetaminophen and codeine (for age >3 years), intravenous acetaminophen, buprenorphine, meperidine, and fentanyl citrate; epidural chloroprocaine, lidocaine, and mepivacaine, continuous epidural clonidine (for intractable cancer pain), and transdermal fentanyl. A handful of other non-steroidal anti-inflammatory medications are approved for the treatment of arthritis and have analgesic effects, including celecoxib, naproxen for children over 2 years, and etodolac and oxaprozin for those over 6 years (Sachs et al., 2008; United States Food and Drug Administration, 2012). It should be noted that of these, aspirin is not used due to concerns for Reye syndrome,

meperidine due to concern about normeperidine induced central nervous system excitation and seizures, and codeine due to its variable metabolism.

Recognizing the slow progress, in 2009, the United States Food and Drug Administration convened a panel of experts to examine the design of analgesic trials in children, including an examination of the propriety of extrapolating safety and efficacy data from adult studies and to recommend the best validated outcome measures for assessing pain (Berde et al., 2012). The standard paradigm used to show the clinical efficacy of analgesic medications is a placebo controlled trial. However, administration of placebos may involve additional exposure to pain by the child participant and therefore constitutes an ethical violation as it exposes the research participant to greater than minimal risk (Shaddy and Denne, 2010). It is not acceptable for a minor research participant to experience untreated pain, even for a very brief period, as that presents increased risk over standard care. While such risk may be deemed acceptable to adults who may evaluate their plights after fully informed consent, this process is not reasonable for minors, especially those who are preverbal and cannot possibly understand the risk–benefit analysis involved. It was concluded that when extrapolation from adult studies is deemed inadequate to demonstrate safety and efficacy in younger patients, alternative research paradigms are to be invoked that eliminate exposure to untreated pain.

Thus, research participation by minors in such a trial is ethically defensible only if (1) there is true equipoise and thus it is not clear that the experimental conditions pose more risk or less benefit than the current standard of care or (2) if the child participant stands to benefit directly by participating in the research. There is broad consensus on this issue, as affirmed by the most recent documents of Declaration of Helsinki (World Medical Association, 2008), the European Union Clinical Trial Directive (European Union, 2008), the Good Clinical Practice Guidelines of the United States FDA (United States Food and Drug Administration, 2011), the International Conference on Harmonisation (International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use, 2000), the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (United States Department of Health and Human Services, 2009), and the Canadian Tri-Council ethical guidelines (Canadian Institutes of Health Research, Natural Sciences and Engineering Research Council of Canada, 2010).

A critical element in evaluating the potential risk of research participation by infants and children focuses on a comparison to the ‘standard of care’. How the latter is defined, however, is quite difficult to determine, as rarely are there published standards and in only some instances are there published guidelines. Even when such guidelines exist, the degree to which there is adherence may vary dramatically. For example, in 2001 the American Academy of Pediatrics and the American Pain Society jointly issued a guideline on the assessment and management of acute pain in infants, children, and adolescents (American Academy of Pediatrics Committee on Psychosocial Aspects of Child and Family Health and American Pain Society Task Force on Pain in Infants, Children, and Adolescents, 2001). To date there is little evidence, however, that the espoused elements have been adopted as a ‘standard of care’.

The issue becomes even more complicated when one invokes local standards. Consider a study of venepuncture in newborns. In Institution A, the local standard is to provide a topical anaesthetic and sucrose. In Institution B, there are no standard interventions for needle pain. A placebo controlled trial is clearly not acceptable in the former setting, but is it acceptable in the latter? What constitutes ‘local’ to define standards, the institution, the immediate geographic area, the region, the country? What if the latter setting is in a less developed nation where innovation in pain medicine has been slow to emerge or almost non-existent? There is no consensus on these important issues at present.

When we consider paediatric pain research in the global context, it is important to take great care in determining the current ‘standard of care’ for the purposes of deciding whether a new intervention warrants study, or for the purposes of instituting adequate controls in a clinical trial (Lavery et al., 2007). The overriding ethical concern is to protect against exploitation of children in communities where the standard of care in pain management is very low or non-existent. For example, it would not be ethically appropriate to investigate a new drug for the management of cancer pain in children in a rural hospital where there are no available drugs for treatment of pain, and include a control arm where children receive no pain treatment because no pain treatment is the current standard of care. However, if the question under investigation is to test improved delivery of an intravenous analgesic in a refugee camp setting, and what is being tested is a low-cost, temperature-resistant bag and line placement kit, one which would not be used in a large urban hospital in a developed country, but would be highly useful in a rural clinic in a developing country, then attention to local context is highly appropriate. In fact, failing to approve such a study on the grounds that the study team is not providing the highest standard of paediatric pain treatment available would deny a specially designed pain intervention which is desperately needed in conflict zones. For this reason, the current thinking on the standard of care question in international research is to adhere to rigorous international principles of research ethics, while allowing some appeal to local standards where a study may be the only means of delivering a targeted, context-specific intervention (Bhutta, 2002).

## Conclusion

‘Above all, do no harm.’ ‘It is a human right to have access to pain management without discrimination, for people in pain to acknowledgment of their pain and to be informed about how it can be assessed and managed, of all people with pain to have access to appropriate assessment and treatment of the pain by adequately trained health care professionals’ (Cousins and Lynch, 2011, p. 2674). These ethical principles form the foundation of the ethical approach to pain in infants and children. Because children are the most vulnerable of people and because they are at the greatest risk for deleterious effects of untreated pain, these issues become heightened. Whether the focus is the provision of pain relief, inclusion in research, or considerations of pain in broad societal and cultural contexts, we must constantly weigh the benefits and risks of our actions. We owe it to the children under our care to rely on science, not personal bias or speculation, in evaluating and treating pain. Failure to do so is a threat to basic ethical standards.

## Case example

Nancy was a 17-year-old girl with advanced leukaemia. She was on the inpatient oncology unit, following a second failed bone marrow transplant with multiple complications, including intestinal graft-versus-host disease (GVHD). Patients in Nancy's situation can often be expected to experience deep somatic pain related to the bone marrow expansion and/or sensitization to engraftment, superficial somatic pain related to chemotherapy or radiation therapy-induced oral mucositis, oral ulcers and skin lesions associated with GVHD, visceral pain related to intestinal GVHD or neutropenic enterocolitis, and neuropathic pain related to drug-induced neuropathies (Niscola, 2008). Nancy had made it clear to providers that she would prefer comfort care to further aggressive chemotherapy regimens, unambiguously demonstrating understanding that she would die. Her mother, however, wanted to pursue experimental treatments in an attempt to prolong Nancy's life, and refused to give parental consent for comfort care, including aggressive pain management, fearing that this might compromise her daughter's response to possible disease modifying agents.

**Ethical questions for consideration:** the primary issue in this context was whether or not opioid analgesics should be reduced in response to parental wishes. Secondary issues for consideration included whether the patient should be given chemotherapy, even though she made it clear she did not want it; including enrolment in a trial of an experimental agent. What would be the best approach for navigating the disagreement between Nancy and her mother?

**Approach:** an ethics committee consultation was sought to identify an optimal approach for the oncology team. While Nancy was not an emancipated or mature minor by legal standards, being several months shy of her eighteenth birthday, she was sufficiently mature to have a voice in even life and death decisions with support from her mother and the medical team. Her wishes to move towards comfort care should be heard and respected. This would include ensuring that everything was done to help Nancy make this decision with support. Patients who are severely depressed and/or in severe pain can have trouble making difficult decisions. The team could ensure that she was as comfortable as possible when making the decision, given adequate social support, and then try re-approaching her to make sure she understands the option of experimental treatment.

**Outcome:** the team tried the described communication approach, and Nancy's mother remained adamant that she wanted to continue fighting for her daughter, not yielding on her stance regarding opioid analgesics. When the psychologist spoke to Nancy in private, she said that she would rather endure pain than spend her final time with her mother in a state of conflict. She decided to go along with the experimental treatment and succumbed to her illness about 8 weeks later.

## CHAPTER 65

---

# Sociodemographic disparities in paediatric pain management: relationships and predictors

Miriam O. Ezenwa and Anna Huguet

### Summary

The purpose of this chapter is to present a narrative review of research studies examining sociodemographic predictors of disparities in pain management in children and adolescents. Findings from this review are conflicting. In the majority of the studies, sociodemographic variables were not statistically significant predictors of disparities in pain management. However, some gaps remain. For the studies in which evidence of sociodemographic disparities exist, it is: (1) not clear whether the statistically significant sociodemographic disparities were also clinically meaningful and (2) in all of the studies reviewed, the goal was to determine predictors of disparities in pain management. Future studies need to focus on determining the clinical meaningfulness of other findings and systematically testing explanatory models for possible sociodemographic disparities in paediatric pain management. Adequately addressing these gaps will help to move forward the science of sociodemographic disparities in paediatric pain management.

### Introduction

Over two decades of research in adults with pain show evidence of racial disparities in pain management. Racial and ethnic minority patients are more likely to receive poor pain management than Caucasians (Cintron and Morrison, 2006; Ezenwa and Fleming, 2012; Ezenwa et al., 2006; Meghani et al., 2012). Much research on the health disparities literature has focused on race/ethnicity as the explanatory factors for the health disparities in pain management. This focus is underscored by the definition of health care disparities provided by the Institute of Medicine (IOM). The IOM defined health disparities as 'Racial or ethnic differences in the quality of health care that are not due to access-related factors or clinical needs, preferences, and appropriateness of intervention' (Smedley et al., 2003, p. 3). While this definition is pertinent and has provided a springboard for honing in on explanatory factors for racial

disparities in pain research, there are important sociodemographic factors, other than race/ethnicity, that could be potential predictors of disparities in pain management both independently and in combination. These factors include age, sex, educational level, geographic location, and income level. Most of the studies reviewed in the IOM report on racial and ethnic disparities in health care were conducted with adults (Smedley et al., 2003). The pioneering work of scholars on pain experiences in children reporting inadequacy of pain control in children (Beyer et al., 1984; Eland and Anderson 1977; Schechter et al., 1986) set the stage for more studies focusing on paediatric pain management, including studies focused on sociodemographic disparities in paediatric pain management. However, there is still limited research.

In this chapter, a non-systematic review aimed to explore several sociodemographic factors (including age, sex, race/ethnicity, insurance status, and residential area) as potential predictors of disparities in pain management in children and adolescents is presented. Pain management is a multidimensional and global construct encompassing concepts such as pain intensity, prescription for pain medication, pain medication used, and satisfaction with pain control. For the purpose of this chapter, we define pain management as receiving pain medications or prescriptions for pain medications. Included in the review were original studies conducted in the US and Europe, in which investigators compared groups on disparities in pain management based on the following sociodemographic factors: age, sex, race/ethnicity, health insurance status, and residential region. The database searched was Medline (PubMed and Ovid Medline). We identified 12 studies that met our inclusion criteria and analysed them using a descriptive analytic approach (see Table 65.1).

### Age-related factors

We identified six studies that examined age-related disparities in pain management. The findings are conflicting. In three

**Table 65.1** Summary of findings on sociodemographic disparities in paediatric pain management

Authors	Design	Sample	Setting	Major findings	Statistics used
<b>Age-related factors</b>					
Zuppa et al. (2005)	Retrospective chart review	2348 children aged between 1-month and 16 years old hospitalized at the PICU in 2002	USA, paediatric intensive care unit (PICU)	The utilization of the most frequently administered drugs (e.g. nalbuphine, morphine, vancomycin, and cefotaxime) differed by age	Univariate (Chi-square) analysis
VanderBeek et al. (2006)	Retrospective cohort study	503 patients 18 years of age or younger with a diagnosis of fractured radius or ulna	USA, tertiary care children's hospital	No statistical age differences were found between those who use conscious sedation and those who didn't; however, younger age of the patient was a significant predictor of conscious sedation use	Univariate (t-test) and multivariate statistical (logistic regression) analysis
Stevens et al. (2010)	Retrospective survey	847 children aged between 3 and 17 years old that receive an headache diagnosis	USA, outpatient setting (including primary and secondary care)	Age was not found to be related with the likelihood of being prescribed an evidence-based medication once a diagnosis is given	Univariate logistic regression
Boyd et al. (2006)	Survey	1017 students in 5th–10th grades (ages ranged from 10 to 18 years)	USA, Detroit-area public school district	No significant age differences in were found in the reporting of use of medical use of pain medications	Univariate (Chi-square) analysis
Ellis et al. (2002)	Survey and chart review	273 children ranging in age from 10 days to 17 years who were on the inpatient unit during the 8-h study period (patients on the psychiatric and the intensive care unit were excluded)	Canada, paediatric teaching hospital	There was no significant correlation between age and the amount of opioid or non-opioid analgesia administered	Correlations
Fein et al. (2010)	Retrospective chart review	363 children younger than 21 years that had lumbar punctures performed in 2003	USA, children's tertiary care hospital	Younger patients received pain management less often than did older patients: ♦ 16 (6.5%) of 246 neonates (0–2 months), 4 (14.3%) of 28 infants (3–18 months), 9 (60%) of 15 preschoolers (19–59 months), and 55 (85.9%) of 64 older children (60 months to 21 years). ♦ 7.2% of children younger than 18 months; 82% of children 19 months or older.	Univariate (Chi-square) analysis
<b>Gender-related factors</b>					
Logan and Rose (2004)	Survey and chart review	102 adolescents aged between 12 and 18 years undergoing surgeries with overnight hospital stay that are typically associated with moderate to severe postoperative pain	USA, large urban paediatric hospital	Patterns of controlled analgesic (PCA) usage, PCA demands or PCA injections did not vary by sex on postoperative days	Univariate analysis (t-test)
VanderBeek et al. (2006)	Retrospective cohort study	503 patients 18 years of age or younger with a diagnosis of fractured radius or ulna	USA, tertiary care children's hospital	Gender was not found to be associated with use of conscious sedation	Univariate (Chi-square analysis) and multivariate (logistic regression) analysis
Boyd et al. (2006)	Survey	1017 students in 5th–10th grades (ages ranged from 10 to 18 years)	USA, Detroit-area public school district	Significant gender differences were found in reporting medical use of prescription pain medication. Girls (17%) were more likely to report medical use of prescription pain medication in the past year than boys (7%)	Univariate (Chi-square) analysis

(Continued)

Table 65.1 (Continued)

Authors	Design	Sample	Setting	Major findings	Statistics used
Ellis et al. (2002)	Survey and chart review	273 children ranging in age from 10 days to 17 years who were on the inpatient unit during the 8-h study period (patients on the psychiatric and the intensive care unit were excluded)	Canada, paediatric teaching hospital	There was no significant correlation between sex and the amount of opioid or non-opioid analgesia administered	Correlations
Taylor et al. (2008)	Survey and chart review	241 medical and surgical patients hospitalized on the day of the audit (no age limits, mean age for boys = 5.9 years, mean age for girls = 4.2 years)	Canada, tertiary and quaternary paediatric hospital	There was no sex difference in the analgesia received	Univariate (Chi-square) analysis
<b>Race/ethnicity-related factors</b>					
Jimenez et al. (2010)	Retrospective cohort study	94 children younger than 18 years old admitted for ambulatory surgery, 47 = Caucasians, mean age = 8.30; 47 = Latinos, mean age = 8.59	USA, ambulatory surgical paediatric hospital	There were racial differences in the receipt of postoperative opioids after tonsillectomy and adenoidectomy surgery	Mann-Whitney U tests, Univariate (Chi-square) and Fisher's exact tests
Sabin and Greenwald (2012)	Online survey	86 academic paediatricians who are faculty, residents, or fellows	USA, large urban research university's primary care, ambulatory, and acute care	Paediatricians' implicit bias was related to prescribing less opioid pain medication for African American children than for Caucasian children after surgery	Pearson's correlations, hierarchical linear regression analysis
Yen et al. (2003) <sup>a</sup>	Retrospective chart review	1030 records representing 3.9 million children younger than 19 years old who presented to emergency department for isolated long bone fracture, 792 records = Caucasians, 111 records = African Americans, 127 records = Hispanics	USA, emergency department	Race did not predict use of analgesics and opioid analgesics	Multivariate logistic regression analysis
VanderBeek et al., (2006) <sup>a</sup>	Retrospective cohort study	503 patients 18 years of age or younger with a diagnosis of fractured radius or ulna, 418 = Caucasians, 85 = African Americans	USA, Tertiary care children's hospital	Race was not associated with receiving conscious sedation	Univariate (t-test) and multivariate statistical (logistic regression) analysis
Taylor et al. (2008)	Survey and chart review	241 medical and surgical patients hospitalized on the day of the audit (no age limits, mean age for boys = 5.9 years, mean age for girls = 4.2 years)	Canada, tertiary and quaternary paediatric hospital	There was no racial difference in the analgesia received by children	Univariate (Chi-square) analysis
Stevens et al. (2010) <sup>a</sup>	Retrospective survey	847 children aged between 3 and 17 years old that receive a headache diagnosis. Sample size for racial groups not provided	USA, outpatient setting (including primary and secondary care)	Race was not related to the likelihood of being prescribed an evidence-based medication once a diagnosis is given	Univariate logistic regression

<sup>a</sup> The same study. A study can fit into more than one category. n/a = not available from original study.

studies, results support age as a predictor of disparities in pain management. In three studies, investigators did not report similar findings.

### Studies where age was related to disparities in pain management

Zuppa et al. (2005) examined whether age was associated with trends in prescription for pain medication in children in the intensive care unit (ICU). All children hospitalized to Child's Hospital of Philadelphia paediatric ICU during the 2002 year were considered ( $n = 2348$ ); data was obtained from the pharmacy database of the hospital. Age was significantly associated with prescription for morphine for children in the ICU (Zuppa et al., 2005). Morphine was prescribed less often for infants (1 month to <2 year) than for older children (2 to <12 years) and adolescents (12 to 16 years) (Zuppa et al., 2005). Similarly, VanderBeek et al. (2006) investigated whether age was associated with the receipt of conscious sedation for pain control for fracture reduction surgery in 503 patients aged 18 years and under. These patients were recruited from a university-affiliated tertiary care children's hospital emergency department (ED). In a multivariate statistical analysis, younger age of the patient was a statistically significant predictor of use of conscious sedation for pain management for forearm fracture reduction (VanderBeek et al., 2006). Likewise, Fein et al. (2010) examined the relationship between age and pain management (local anaesthetics and sedation) received during the lumbar puncture procedure.

They retrospectively reviewed the records of all patients younger than 21 years who had received this procedure during the year 2003 at a large urban children's hospital. Their sample included 363 children. They found that younger patients received pain management less often than did older patients: 16 (6.5%) of 246 neonates (0–2 months), 4 (14.3%) of 28 infants (3–18 months), 9 (60%) of 15 pre-schoolers (19–59 months), and 55 (85.9%) of 64 older children (60 months to 21 years) (Fein et al., 2010).

### Studies where age was not related to disparities in pain management

Ellis et al. (2002) examined the relationship between age and analgesic when surveying all children and their parents who were hospitalized in a paediatric teaching hospital in eastern Ontario during the 8-h data collection period. Children hospitalized on the psychiatric unit and the intensive care units were excluded. Their sample included 273 children aged between 10 days and 17 years old. They found that there was no statistically significant correlation between age and the amount of opioid or non-opioid analgesia administered to the children (Ellis et al., 2002). Similarly, Boyd et al. (2006) in a study conducted with 1017 students in fifth to tenth grade (ages ranged from 10 years to 18 years) examined the use of pain medication for medical and non-medical purposes. They found that as grade level increased so too did prevalence rates of medical use of pain medications, but the differences were not statistically different (Boyd et al., 2006). Finally, Stevens

et al. (2010), in a retrospective study including 847 children aged between 3 and 17 years old, explored whether there were sociodemographic differences in the management of children's headache. They found that age was not related to the likelihood of being prescribed an evidence-based medication for headache (Stevens et al., 2010).

Taken together, the findings of the studies that examined age-related disparities in paediatric pain management are inconsistent. Reasons for this inconsistency could be multifaceted. The wide range of age of children included within individual studies could be problematic because developmentally, these children differ in their ability to communicate presence of pain. It was not clear whether age-appropriate pain assessment measures were used for the diverse age range of the sample. Another probable explanation for the inconsistent findings could be related to type of pain. Studies have been conducted with patients with varied types of pain (headache, menstrual cramps, urological, surgical, and other unspecified types of pain). Also, the context where the pain is experienced may explain these inconsistent findings. Studies are focused on outpatients, patients undergoing a surgical procedure, or in an ICU setting located in different institutions. Hence, the decision to administer a particular dose of pain management resides with the provider as well as the culture of the institution. Provider variables such as opioidphobia and inadequate knowledge and training about pain management or lack of supporting pain management policies contributes to poor pain management (Bashayreh 2011). Consequently, the 2011 IOM report *Relieving Pain in America* recommends more training and education of both current and future health care providers on pain management skills (Institute of Medicine, 2011). Patient and caregiver training are also needed to overcome misconceptions about use of opioids, which have been reported as barriers to adequate pain management in the adult pain populations (Ward and Hernandez 1994; Ward et al., 1993).

The age groups likely to receive disparate pain management differ. For instance, VanderBeek et al. (2006) found that younger children were more likely to receive prescription pain medication. On the other hand, in Fein et al.'s (2006) study, younger children were less likely to receive prescription pain medication. The pain management goal must be to administer or provide prescriptions for pain medications that are appropriate for patients' pain level and age. To reduce and/or prevent age-related disparities in paediatric pain management, it is necessary to use age appropriate tools, such as the Poker Chip Tool for children from age 3 to 4 by Hester et al. (1990), the Faces Pain Scale- Revised for children from age 4 to 12 by Hicks et al. (2001), or the Numerical Rating Scale for children aged 8 years or older (von Baeyer et al., 2009). See McGrath et al. (2008) for evidence-based recommendations for the use of measures and assessment strategies for pain for different age groups. It is also important to use evidence-based pain management guidelines and protocols to adequately assess and treat children's pain.

## Sex-related factors

In five studies, investigators examined sex differences in pain management of paediatric patients. One study supports sex as a predictor of disparities in paediatric pain management. The other four studies did not support this finding.

## Study where sex was related to disparities in pain management

We have earlier described in more details Boyd et al.'s (2006) study. Boyd and colleagues also found that sex was related to inadequate pain management. They found that there was a statistically significant sex disparity in the report of medical use of prescription pain medication. Girls (17%) were more likely to report medical use of prescription pain medication in the past year than boys (7%) (Boyd et al., 2006). Boyd and colleagues when surveying the 1071 middle and high school students did not ask them for their levels of pain, so they could not control for pain levels when comparing both sex groups.

## Studies where sex was not related to disparities in pain management

Reporting on the sex-related findings in the Ellis et al. (2002) study described earlier, findings show that there was no statistically significant correlation between sex and the amount of opioid or non-opioid analgesia administered (Ellis et al., 2002). No sex differences in pain levels were reported, but findings show no significant correlations between pain intensity rating provided by children or professional and amount of opioid or non-opioid analgesia prescribed and administered (Ellis et al., 2002). In another study, Logan et al. (2004) conducted a study with 102 adolescents aged 12 to 18 years who were undergoing surgeries to examine sex differences in post-operative use of patient-controlled analgesia (PCA). Although girls reported statistically significant higher low and average pain scores than boys, boys and girls did not differ significantly on total PCA usage, PCA demands, or PCA injections after surgery (Logan and Rose, 2004). Further, in the VanderBeek et al. study described earlier, in a univariate statistical analysis, sex was not associated with use of conscious sedation for pain control (VanderBeek et al., 2006). Multivariate results also show that sex was not a significant predictor of conscious sedation use (VanderBeek et al., 2006). Finally, Taylor et al. (2008) in a study with 241 medical and surgical inpatients to determine the adequacy of pain management in a sample of hospitalized children found no sex difference in the analgesia received (Taylor et al., 2008).

In sum, although sex-based disparities have often been reported in prevalence of pain and the adjustment to the pain especially around puberty with more girls reporting more pain and its impact on daily activities (Huguet and Miro 2008; King et al., 2011; Kroner-Herwig et al., 2007; Mattila et al., 2005), sex disparities tend to be observed in use of prescribed medication. The fact that girls may be more prone to develop more frequent and severe pain but use less prescribed pain medication than boys may suggest sex differences in the response to pain management as suggested by Fillingim et al. (2009) or sex differences in attitudes to drug use.

## Racial- and ethnic-related factors

We identified seven studies in which investigators examined race/ethnicity as predictors of disparities in pain management. The studies reported mixed results. We have categorized them into two rubrics: studies supporting racial disparities in pain management and studies not in support of racial/ethnic disparities in pain management.

### Study where race/ethnicity was related to disparities in pain management

Jimenez et al. (2008) in a retrospective cohort study of 94 children, 47 Caucasian and 47 Latino patients presenting to the ambulatory surgical unit in a children's hospital, examined whether racial disparities exist in use of postoperative opioids. Latino children received 30% less postoperative opioids than Caucasian children presenting for tonsillectomy and adenoidectomy (Jimenez et al., 2010). Similarly, Sabin and Greenwald examined the role of paediatricians' implicit bias on pain management recommendation for children's surgical pain with 86 academic paediatricians who are faculty, residents, or fellows in large urban research university's primary care, ambulatory, and acute care settings. Race/ethnicity was a statistically significant predictor of narcotic prescriptions (Sabin and Greenwald, 2012). Paediatricians prescribed less opioid pain medication for African Americans than for Caucasians after surgery (Sabin and Greenwald, 2012).

### Study where race/ethnicity was not related to disparities in pain management

Yen et al. (2003) with a nationally representative sample of children's records who presented in the ED, Caucasian,  $n = 792$ , African American,  $n = 111$ , Hispanic,  $n = 127$ , determined whether race was associated with receiving analgesics to control pain related to isolated long-bone fracture. After controlling for confounding variables (health insurance type, hospital owner type, geographic region, and survey year), there was no statistically significant difference between African Americans, Hispanics, and Caucasian for using analgesics and opioid analgesics for isolated long-bone fracture (Yen et al., 2003). Likewise, VanderBeek et al. (2006) in a retrospective cohort study of children presenting in a tertiary care children's hospital, Caucasian,  $n = 418$  and African American,  $n = 85$ , found that race/ethnicity was not associated with receiving sedation for pain management for forearm fracture reduction (VanderBeek et al., 2006). In the Taylor et al. study described earlier, there is no racial/ethnic difference in the analgesia received (Taylor et al., 2008). In the same way, Stevens et al. in a retrospective study used two nationally representative samples of 847 children from outpatient setting, including primary and secondary care settings to examine whether there were race/ethnic disparities in management of children's headache. The authors did not provide the racial breakdown of their sample. Race/ethnicity was not significantly related to receiving evidence-based medication for the management of headache (Stevens et al., 2010). Finally, Brodzinski et al. examined race/ethnic disparities in pain management of Caucasian,  $n = 2128$ , Minority,  $n = 1426$  children who presented to the emergency department for laceration repair. After controlling for other sociodemographic (age, gender, and socioeconomic status (SES)) and clinical (triage acuity, physician type, length of laceration, complexity of repair, time of day, body site of laceration, and use of topical anaesthetics) variables, there was no significant association between race/ethnicity and receipt of pharmacological procedural sedation in children who underwent laceration repair (Brodzinski et al., 2010).

In summary, although the findings related to race/ethnic disparities in paediatric pain management studies were inconsistent, the majority found no statistically significant racial or ethnic differences in the pain management of children.

## Health insurance-related factors

In two studies, investigators examined patients' health insurance status as a predictor of disparities in pain management. In both studies, patients' health insurance status was not related to disparities in pain management.

Brodzinski and colleagues, in the study described earlier, included 3554 children in research to examine health insurance status, as a predictor socioeconomic disparities in pain management of children who presented to the emergency department for laceration repair in an urban tertiary-care children's hospital emergency department. There were 1946 children with private health insurance and 1608 with public or no health insurance. After controlling for sociodemographic (age, gender, and SES) and clinical (triage acuity, physician type, length of laceration, complexity of repair, time of day, body site of laceration, and use of topical anaesthetics) variables, there was no statistically significant association between health insurance status and receiving procedural sedation in these children (Brodzinski et al., 2010). Similarly, Stevens et al.'s retrospective study, described earlier, used two nationally representative samples to examine whether there were disparities in management of children's headache based on health insurance status. The authors did not provide the breakdown of children represented in their four insurance status categories: private, Medicaid, self-pay, and other. They found that health insurance status was not statistically related to receiving evidence-based medication for the management of headache (Stevens et al., 2010).

In summary, health insurance status was not found to predict disparities in pain management. These results support the ethical standards and acceptability that all children in pain receive management regardless of health insurance status.

## Residential-related factors

In only one study did investigators examine the relationship between residential region and disparities in paediatric pain management. Yen et al. (2003), with a nationally representative sample of 1030 children's records, examined disparities in the receipt of analgesics for isolated long-bone fracture pain based on residential region of children who presented in EDs. After controlling for confounding variables including age, payment method, hospital type, survey year, and metropolitan statistical area status of the hospital, children from the South and West region of the United States were significantly more likely to receive opioid analgesics than children from the Northeast for isolated long-bone fracture (Yen et al., 2003). Although there was a difference in paediatric pain management based on residential region, it's not clear what this finding from one single study represents. We cannot put any emphasis on this one study until more evidence emerges in this area.

## Conclusion

There is accumulating evidence about the contribution of sociodemographic factors to disparities in paediatric pain management. However, the results are inconsistent (see Table 65.1). Unlike the findings in the adult population, in the majority of the studies that focused on children, evidence did not support sociodemographic factors as predictors of disparities in paediatric pain management. For the studies in which evidence supports sociodemographic

factors as predictors of disparities in pain management, we have confidence in the interpretations of the results. Investigators controlled for several confounding variables that could have obscured the interpretation of findings, e.g. age, gender, SES, triage acuity (Brodzinski et al., 2010); health insurance type, hospital owner type, geographic region, and survey year (Yen et al., 2003). However, some gaps remain. Future studies should provide evidence of clinical significance of the sociodemographic disparities in paediatric pain management. Although, the disparities might be statistically significant, they may not be clinically meaningful. This knowledge is critical because evidence of clinically meaningful sociodemographic disparities in paediatric pain management have practice implications. For example, it could suggest medical errors on the part of the providers that require serious action. Pain relief is a fundamental human right (Brennan et al., 2007). Consequently, inadequate pain management induced by sociodemographic differences is a medical error that leads to unnecessary pain and suffering (McNeill et al., 2004). Further, all of the studies have focused simply on exploring potential sociodemographic disparities in paediatric pain management without suggesting explanations for those disparities when reported. Based on these findings, we make some recommendations that will help move forward the science of sociodemographic disparities in pain paediatric pain management. We recommend that investigators should: (1) systematically and prospectively examine factors that explain sociodemographic disparities in paediatric pain management, (2) determine whether the sociodemographic disparities in paediatric pain management are clinically meaningful, and (3) examine differences using a theoretical model that may provide information on the cause of any disparities. This approach will provide evidence to develop interventions that address both patient-related and provider-related factors that contribute to sociodemographic disparities in paediatric pain management.

Our findings have education, research, and policy implications. In order to improve paediatric pain management, there needs to be more education and training for health professionals who care for children and adolescents in pain. Provider training could focus on how to incorporate pharmacological and non-pharmacological interventions and on the invaluable skills of assessing the effectiveness of the intervention to improve pain management in children. Researchers should develop interventions that focus on eliminating sociodemographic disparities in paediatric pain management. Research that examine patient-provider variables such as communication skills, racial or sex concordance, and trust that could be barriers to adequate pain treatment are desperately needed. These patient-provider factors could moderate the relationship between sociodemographic variables and pain outcomes in this population. Finally, engaging policymakers during several aspects of research in paediatric pain management has a merit. It will serve as an impetus to policymakers to advocate for more research funding for paediatric pain management to reduce pain severity and improve quality of life for these patients.

#### Case example: sociodemographic issues related to paediatric pain management

BJ is a happy 13-year-old African American girl whose personality is larger than life. She lives in a subsidized housing apartment in Texas with her single mother and two brothers. BJ is

a typical tomboy who enjoys playing soccer with her brothers. Her love for soccer helped her to secure a position as the team captain of the girls' soccer team in her middle school. Around thanksgiving holiday, BJ started complaining of headaches that eventually increased in frequency and intensity. Currently, BJ suffers numerous headaches per month and rates them as 7 or 8 on a scale of 0 to 10, where 0 is no pain and 10 is pain as bad as it can be. Over-the-counter (OTC) pain medications do not abate her frequent headaches. Her mother feels frustrated because of loss of work days when BJ is sent home from school or she needs to take BJ to the ED, which is now increasing in frequency. She asked BJ's doctors why nothing much is done to help BJ. She learned that her public health insurance does not provide coverage for a wide range of effective interventions. BJ's prescriptions for pain medications consist of only OTC and weak opioids such as codeine. These pain medications are not strong enough to relieve the severe headaches that BJ often suffers and treatments options other than medication are not available for her. Consequently, BJ suffered in pain, became depressed, and dropped out of school and the soccer team she loved. BJ was beside herself in anger and frustration after a visit from her friend, KC, a 14-year-old Caucasian boy. KC told BJ how well triptans and biofeedback were able to reduce his migraines. His father gave him strong opioid pain medication that greatly relieved his pain. BJ wonders if the poor pain management she receives was because she is a poor African American girl who lives in a poor housing unit and her mother cannot afford better pain management resources. She thought it was unfair but at the same time feels helpless to change her situation.
